THE TECHNOLOGICAL UNIVERSITY

By Dr. S. C. CURRAN, F.R.S.

Royal College of Science and Technology, Glasgow, C.1

School Education

OUR schools, particularly the Scottish schools, are in a critically dangerous state so far as the flow of properly trained students to the universities is concerned. This is affecting the number of entrants to science and engineering, which are the principal fields of study in a university biased towards technology. Early action of a radical kind is required if pupils in our senior secondary schools are to be given a fair opportunity to enter the most expanding part of the national education scene. Most schools seem to be desperately short of staff adequately trained in mathematics and physics, and to a lesser extent chemistry. The two fundamental sciences of physics and chemistry must be given the status of full subjects and staffed accordingly as otherwise physicists are penalized.

The length of training, four years in an honours course, followed by a year of study at a training college, is much less attractive than the shorter passage to teaching in England. The deadlock must be broken, as otherwise Scottish pupils will suffer severely by missing the opportunities available to them in science and technology. Salary differentials of an attractive nature might be one answer, and this might be effected by the special staffing of advanced-level schools set up at chosen centres. These schools could take pupils from approximately the Ordinary Level to the Advanced Level and the Scottish and English patterns thus brought nearer to equivalence in spite of the special difficulties encountered in Scotland. These stem to a large extent from the fact that the population is more widely dispersed so that the sixth form is a sham in most instances. It is impracticable and very expensive to set up good sixth forms in the majority of Scottish schools.

The higher-level education in technology depends on school performance in mathematics, physics and chemistry, and the drive towards specialization in these subjects in the English schools has been examined recently by scientists who advised some reduction in extreme specialization in all fields. In Scotland there is no specialization in this sense, and whereas the advice offered to English schools was to cut the study in science or classics or any other single specialized field to half the total, the Scottish schools simply do not, indeed can not, offer that much. If they did the staffing position would become still more desperate.

Some outlet for the natural appetite of pupils of 16–18 years of age must be offered. They are then at one of the peaks of their mental activity, they are intensely interested in fashioning their future career and the lack of adequate facilities for the young people in the upper reaches of our schools is bound to depress and thwart them. Many are being lost and more will be lost unless we find a plan and are prepared to carry it out immediately. There is no reason to decry the wish of the young people to choose their subjects with a vocation in mind. Interest is the sure key to learning and in turn to understanding. If the right subjects are taught well it is all to the good if the vocational aspect is obviously attractive. This is one of the great points of strength of mathematics and science. They are necessary for entry to so many fields in which trained men and women are required.

A Modern University

There seems to be an obvious need for a form of university that is not, so far, part in its own right of our British university system. This might be termed the technological university though this is something of a misnomer. If one takes a thoroughly acceptable form of definition of a university training it is clear that an education in science and engineering of the right kind satisfies the conditions extremely well. A proper understanding of these subjects is both cultural and vocational at one and the same time. The technologist requires too a 'rounding-off' of his education and this can be very appropriately provided by study of the social sciences or humane studies in which a keen interest is for him a natural extension of his more professional studies. This is recognized in universities of this type, for example, the Massachusetts Institute of Technology, where those responsible for the courses in the social studies are of the highest calibre. In the hands of such real experts in their fields the courses are of great value. In such a university, too, the reverse is readily possible although not so frequently practised. A study of the social sciences with a good grounding in science or engineering offers an excellent kind of degree course.

Such an institution has great strength in its freedom from some of the difficulties facing the really comprehensive multi-faculty universities. The administration of those is a task of great difficulty, but there could be some uniformity of purpose in the more modern form of university. This could enable it to organize more easily inter-departmental programmes at both undergraduate and postgraduate level.

---

* Substance of a lecture delivered before the Royal Society of Edinburgh on March 6.

Research

At present there is great danger that universities may lose their traditional role of leadership in fundamental research and this might well be taken over by large research groups under governmental control. A university operating in science, engineering and the social sciences has a form lending itself to the proper handling of real research programmes, and so research leadership of a more valuable type could be retained.

Such a university gives its graduates a real appreciation of the wholeness of our Western civilization. The departments would have a real sense of their common aim. The cultural target would be clearly established. The subjects would not be treated as segments of our intellectual heritage operating in comparative isolation, a situation not uncommon in our universities.

The position in Britain is not at all satisfactory. In the United States and on the Continent of Europe the situation has been faced squarely during the past century. Large institutions devoting themselves to science and technology and associated fields such as the humane sciences have long granted their own degrees and stood alongside other types of university. Thus we have, for example, the Massachusetts Institute of Technology, and institutes of comparable standing at Zurich and Aachen. The industrial strength of the nations depends more and more on such institutions and they are an absolutely vital part of the higher educational system. We ignored the vital role of science and scientific research so that France and later Germany far excelled us. About a century ago we finally decided to turn professional and leave amateurism in pure science, and our universities admitted the sciences. But applied science and engineering have never been adequately recognized and we must act now, see to the full recognition and acceptable status. This will mean that the training of scientists and technologists can be organized on an adequate scale to satisfy the vital needs of Britain for graduates and for thoroughly good research.

The number of scientists and engineers required is such that the balance of the orthodox form of university structure would be upset. Some five or so applied scientists are required for each pure scientist; but the faculty of science itself is usually large as faculties stand. Clearly it would be wise to recognize that the real demand cannot be met by existing universities, and that in meeting it well it is wise to set up universities of a pattern suitable to meet the need in the most appropriate way. The new institution will more readily provide the men with the type of education that is truly of the best university type even if the institution is not of the orthodox pattern of universities with comprehensive subject coverage. It has as its primary objective the provision of a true university education in a limited number of fields without the weaknesses inherent in one and the same place attempting to provide it in all fields. Conditions are such that to try to do so in all fields, especially by including technology as one of the many, is to court disaster.

We live in a technological age, and the number of technologists required should only be limited in the future by the number of those with the adequate capacity for the subjects and the taste for them. Given an education of an integrated type the men graduating from such a university will scarcely be aware of the so-called division between the two cultures. They will have learned to absorb both and should continue to do so throughout their lives. These are the views which hold sway at the Royal College of Science and Technology, Glasgow, and we have applied them already in our courses and we will apply them increasingly in the future.

SIGNIFICANCE OF CARBONACEOUS METEORITES IN THEORIES ON THE ORIGIN OF LIFE

By Prof. J. D. BERNAL, F.R.S.

Birkbeck College, University of London

At the meeting of the New York Academy of Sciences on March 15, 1961, B. Nagy, W. G. Meinschein and D. J. Hennessy reported their findings of mass spectrographic analysis of carbonaceous material from the Orgeuil meteorite of 1864 (*Nature*, 189, 967; 1961). They concluded from this that the distribution of hydrocarbons in the high-temperature distillate was so similar to that found for animal products such as butter or organic materials in sediments as to justify the conclusion, admittedly preliminary, "that biogenic processes occur and that living forms exist in regions of the universe beyond the earth".

It was this conclusion that, quite naturally, gave rise to much publicity. There is a danger that this will, in serious scientific circles, cause the observations of the three authors to be overlooked, which would be a great mistake, for whatever the interpretation put on them they are of cardinal importance to science.

It would be premature to discuss here the detail of these observations in advance of the publication of the full report; but enough has appeared to understand their general tenor, and it is important that they should be widely known, for a reason which will be discussed more fully later, otherwise careless study of other meteoritic material may well destroy irreplaceable evidence.

The study of carbonaceous material in meteorites is not new. The first detailed analysis to be published was that of G. Mueller in 1952 on the Cold Bokkevelt meteorite, which seems similar to that in the Orgeuil meteorite. Using conventional methods of analysis, he showed that a large part of the black material was soluble in organic solvents and the recovered material showed a somewhat unusual composition: hydrogen, 8 per cent; carbon, 24 per cent; nitrogen, 4 per cent; oxygen, 49 per cent; sulphur, > 9 per cent; chlorine, 6 per cent. The high oxygen content suggests a complex organic acid. If it was to be compared with any material produced by living systems, it would be with the humic acid of peat. Mueller drew no cosmic conclusions from his work, and it attracted little attention at the time.

The recent work is consistent with this picture but completes it in a significant way. Using mass spectrographic analysis of a distillate of the meteorite, they found the largest portion of the 250°–400° C. fraction to consist of paraffinoid hydrocarbons of carbon numbers ranging from 15 to 24 with peaks at 18 and 23 carbon atoms, as well as some cycloparaffins. This distribution is similar but by no means identical with that found by the authors for butter and recent sediments using the same apparatus.

There can be no serious doubt that the Orgeuil material is from a genuine meteorite, and that it has been examined in an uncontaminated state. The mass spectroscopic evidence should also be accepted in view of the experience of Dr. Meinschein in precisely this type of work in the petroleum field.

The major question that arises, therefore, is as to the interpretation of the results. Though the mass spectroscopic evidence indicates a composition of meteoritic hydrocarbons within the range of those given by material of organic origin on the Earth, from this it only follows that the meteorite material *may* be of organismal origin and not that it *must* be so. The actual hydrocarbon fragments are admittedly artefacts produced from some more complex source by the rather drastic distillation and electron bombardment processes. However, as there is little possibility that they are synthesized by these processes, the original material must contain paraffinoid elements similar to those produced in living matter.

Here the onus of proof is on synthetic chemists who must show that these have been, or could be, produced by purely inorganic condensations from smaller carbon-containing molecules. A possible mechanism for this is suggested below but requires experimental test.

The vital question could be settled once and for all if specific molecules such as porphyrins or nucleotides were found. A counter indication at the moment is the extremely low phosphorus content of the meteorite.

Pending a settlement of this question by analytical or synthetic methods, it may be worth while, in order to direct further experimentation, to speculate on alternate hypotheses for the formation of carbonaceous material in meteorites. These alternatives are either that they are produced by some form of life or that they are produced by wholly inorganic processes.

If the material is derived from life, this must have occurred on the planetary parent body from which by general consensus we believe meteorites to have been derived by fragmentation.

The time of flight of the Orgeuil stone has not, so far as I know, yet been measured; but it is unlikely to be more than 200 million years on analogy with other meteorites. This would mean that in recorded geological time there must have existed a planet on which life processes had evolved sufficiently to produce long-chain hydrocarbons.

Meteoritic parent bodies, however, as most recently demonstrated by E. Anders[1], appear to be located in the asteroid belt between Mars and Jupiter, a region where mean surface temperatures are approximately – 50° C. This would not appear to permit liquid water and hence any chemical evolution. Further, even if hot enough they would not be large enough to hold water vapour gravitationally and, therefore, would be dry bodies like the Moon.

The only likely place for the genesis of such hydrocarbons would be a planet the size of the Earth at about the same distance from the Sun. Why not the Earth itself, if we are not allowed any longer to postulate Pythagoras' anti-Earth? The Orgeuil meteorite would then be a piece of primitive Earth shot off some hundreds of millions of years ago and again united to its parent body. Even more fanciful would be the idea that the stone derives from an earth-like planet of another solar system.

If the first alternative appears difficult to accept, the second only avoids some of these difficulties to encounter others. In this hypothesis, following Mason[2], the nuclei of condensation would be the little platelets of hydrous iron magnesium silicate formed directly from the solar gases. Originally, in the cool and opaque dust cloud surrounding the Sun, these would accumulate ice, methane, ammonia and hydrogen sulphide in solid form from the more volatile solar gas components. As the cloud cleared by particle agglomeration, these would evaporate leaving, however, a thin skin of polymerized carbonaceous material produced by the action of cosmic ray and solar particles. In favour of this we have the evidence from Duchesne[3] that carbonaceous meteorites contain free radicals. There is also the observation of G. Mueller[4] that the very similar Cold Bokkevelt meteorite resisted boiling hydrofluoric acid for 140 hr., indicating the complete carbonaceous covering of each small silicate particle.

The crucial question is now whether it is possible to imitate the carbonaceous material of the meteorites by the action of radiation-work here for atomic piles and high-energy machines. If this question can be answered in the affirmative, the carbonaceous meteorites become the *primary accumulation* of elements and free energy for the first synthesis of life *on this Earth*[5] rather than the end products of chemical evolution on some other celestial body, which in any event would simply remove the problem of the origin of life by another great move in time and space.

We can speculate about these problems now, but what is clearly needed is more careful experiment and critical evaluation. Thanks to the pioneer work of Nagy, Meinschein and Hennessy, there is every reason for believing that this will take place in many laboratories throughout the world, but if this happens without planning and co-operation the results may be scientifically disastrous.

There are probably not more than 50 kgm. of carbonaceous meteorite material in the world to-day; it could easily be used up in a year if each investigator looking for one thing at a time—be it helium-3, porphyrin or radicals—uses up a piece of meteorite in a way to make it unavailable to other workers. What is needed is a carefully worked out flow-sheet needing the minimum of material, so arranged that only the best equipped and experienced workers do the operation of analysis in which they are expert. This would require an overall organization that fortunately is to hand in the Commission on Space Research and in its constituent organizations in other countries.

The study of meteorites is one involving nearly all the disciplines in science and, like the International Geophysical Year, could be another excellent trial ground for co-operation in science.

NEWS and VIEWS

Bacteriology at St. Bartholomew's :

Prof. L. P. Garrod

For more than thirty-five years bacteriology at St. Bartholomew's Hospital has been associated with the name of L. P. Garrod, who is due to retire in this academic year. During all these years, Prof. Garrod has contributed much in the field of medical bacteriology. Anyone who knows the cramped conditions in which he has worked will be astonished at what he has achieved. Prof. Garrod belongs to a generation in which it was still possible to be a first-class pathologist and bacteriologist, as well as a first-class clinician, and any who remember his lectures on 'worms' will agree that he is also no mean helminthologist. He has contributed many important articles or chapters in almost every branch of medical bacteriology—for example, actinomycosis, staphylococcal infections and endocarditis, to mention only a few. But Garrod has also kept abreast or even ahead of new developments. In recent years he has often led the way in the critical appraisal of new antibiotics and sometimes in exposing exaggerated claims that have been made. He has been especially interested in the validity of laboratory tests for the sensitivity of bacteria to antibiotics, and he has always tried to show how these tests should be employed so as to give information which may be of real clinical value. He has also been interested in the mode of action of antibiotics, in the differences in bacteriostatic and bactericidal activity, and in the development of antibiotic-resistant strains. He has exerted a profound influence on the development of bacteriology during what may prove to be the first phase of the era of chemotherapy, which is now showing signs of passing from a medical to a more biochemical and biological phase. It is to be hoped that Prof. Garrod will continue after his retirement to work in the field in which he has contributed so much.

Dr. R. A. Shooter

Dr. R. A. Shooter, whose appointment to succeed Prof. L. P. Garrod as professor of bacteriology starts in October 1961, has already made his mark in the field of hospital bacteriology. In much of his work he has been closely associated with Prof. Garrod, but in recent years he has developed a special interest in problems of cross-infection and hospital hygiene and epidemiology. This work has been especially important at a time when surgical wards and theatres and medical wards, too, have been invaded by antibiotic-resistant staphylococci and other organisms, and when the first flush of success in the antibiotic era has given place to a more sober realization of what antibiotics can and cannot be expected to do. Dr. Shooter has paid great attention to problems of staphylococci, of masks, of air and dust and of ventilation in the spread of staphylococcal infection. In the past few months Prof. Garrod and Dr. Shooter have combined with Dr. Blowers and Prof. Williams to produce an excellent book on hospital infection. This has met a very real need and is a fitting conclusion to years of fruitful co-operation in this special branch of bacteriology.

Technical Operations at the International Atomic Energy Agency :

Dr. P. L. Balligand

Dr. Pierre Louis Balligand has been appointed to succeed Dr. Hubert de Laboulaye as deputy director general in charge of the Department of Technical Operations of the International Atomic Energy Agency. Dr. Balligand, who is a graduate of the Ecole Polytechnique, is at present head of the Division of Large Research Reactors of the French Commissariat à l'Energie Atomique, which was established to run the operation of the test reactor *EL* 2 and the start-up and development of the high-flux reactor *EL* 3. The service will also include the operation of the test reactor *Pegase* at the new French reactor centre at Cadarache. Dr. Balligand was concerned with the organization of a test reactor research group, the function of which was normalizing in-pile experiments and arranging dosimetry and flux measurements studies. This group has collaborated closely with similar efforts in other European countries ; an experimental programme is now being organized in Belgium at Mol, and others are being developed in Italy, Switzerland and Yugoslavia. Reactor safety regulations have been a main concern of Dr. Balligand and the development and application of the first provisional safety measures for experimental reactors at Saclay were his responsibility. However, these regulations are now the responsibility of a Reactor Safety Committee, of which Dr. Balligand was a member. Dr. Balligand will commence his new duties towards the end of March, when Dr. de Laboulaye returns to a senior position with the French Commissariat à l'Energie Atomique.

Industrial Engineering at Toronto :

Prof. Arthur Porter

Dr. Arthur Porter, dean of the College of Engineering in the University of Saskatchewan, has been appointed the first professor of industrial engineering in the University of Toronto. Prof. Porter is an authority on the electrical control systems which, among other things, make possible large-scale automation of industry. He worked in Toronto during 1949–55 as head of the research division of Ferranti Electrical, Ltd., the company which installed the University of Toronto's first large electronic computer in 1952. Before becoming dean at Saskatchewan in 1958, he was professor of light electrical engineering at the Imperial College of Science and Technology, London (see *Nature*, 181, 1178; 1958). He is the first member of the University of Toronto staff to be associated solely with the new course in industrial engineering, which superseded the engineering and business course two years ago. Until now, the industrial engineering course has been administered and staffed entirely by professors attached to the Mechanical Engineering, Mathematics and other Departments. The new course covers areas of fundamental engineering and science, but is heavily weighted toward mathematics. Its undergraduates study operations research, electronic data processing, control theory, numerical analysis and probability and statistics. They also are introduced to modern work in organizational structure, financial control and industrial psychology.

Agricultural Economics at Nottingham :

D. K. Britton

Mr. D. K. Britton, at present general manager, Market and Economic Research Department, Massey-Ferguson (U.K.), Ltd., has been elected to the new chair of agricultural economics at the University of Nottingham as from June 1. Mr. Britton will be head of the Department of Agricultural Economics and a provincial agricultural economist. Mr. Britton graduated at the London School of Economics and shortly afterwards was appointed statistician in the Ministry of Agriculture and Fisheries. From 1947 until 1952 he was a member of the research staff of the Agricultural Economics Research Institute, University of Oxford, after which he accepted an appointment with the United Nations Food and Agriculture Organization in Geneva. In this work he travelled widely in Eastern and Western Europe. In 1959 he returned to the United Kingdom to take up his present position.

Security Measures and Freedom of the Individual

An immediate repercussion of the recent spy trial in London was the announcement in the House of Commons on March 23 that the First Lord of the Admiralty would set up a committee of inquiry to ascertain what security weaknesses existed at the Admiralty Underwater Weapons Establishment and to determine where responsibility lies for such breaches of security as have occurred. The Prime Minister, in replying, showed himself fully aware of the difficulty of holding the balance between national security and the freedom of the individual from perpetual surveillance in a free society. He quoted the Lord Chief Justice's words that ultimate security must depend always on the honesty of those who are put in a position of trust; and if a person suddenly and for gain becomes dishonest, no security measures are adequate. Existing security procedures which apply to the Government Services were reviewed comprehensively by the Committee of Privy Councillors in 1956, and Parliament accepted these procedures as appropriate and adequate for their purposes. They are kept continually under review by the appropriate authorities, and to adopt a different procedure would involve a much greater range of inquiry about the activities of individuals. Nevertheless, Mr. Macmillan undertook to look at the matter again, and to consider whether the procedures laid down in 1956 should be tightened in any way.

The International Union of Geological Sciences

At the twenty-first International Geological Congress meeting held in Copenhagen on August 23, 1960, it was decided to form an international union of geology. The International Union of Geological Sciences was founded by thirty countries at a Constitutive Assembly held at Unesco House, Paris, on March 9–10, 1961. The statutes prepared by the Organizing Committee in Stockholm in December 1960 were ratified, and the following Executive Committee was elected: *president*, J. M. Harrison (Canada); *vice-presidents*, I. I. Gorski (U.S.S.R.), L. Hawkes (United Kingdom), A. R. Lamego (Brazil), J. Lombard (France), B. C. Roy (India) ; *secretary*, Th. Sorgenfrei (Denmark); *treasurer*, J. A. Dons (Norway). The object of the Union is to promote international co-operation in geology, and of geology with other sciences. Application has been made for admittance to the International Council of Scientific Unions at its meeting in London in September 1961.

Export Problems and the Technical Chemist

A booklet issued by the Association of British Chemical Manufacturers (86 Strand, London, W.C.2), entitled *European Free Trade Association: Origin Rules, Certification and Segregation of Stocks*, comprises a report of meetings in London and Manchester in June 1960. It includes addresses by W. A. M. Edwards on recent developments concerning the European Free Trade Association and the Common Market, by W. G. Harrold on the need for origin rules and by H. W. Vallender on the operation of the value rule and the associated basic materials ; and also N. E. Wallace's paper on the operation of the process rules for organic chemicals, and for other sectors of the chemical industry, and those of L. J. White on the certification and control of the origin of goods and on the segregation of stocks of materials by accounting methods. There is also a note on the provision of information on origin of chemicals purchased for use in the manufacture of products for export to the European Free Trade Area. Intended primarily to assist those concerned in these export problems, these papers, and particularly that of N. E. Wallace, illustrate the technical difficulties with which the chemical manufacturer has now to contend. There is also a short bibliography of official publications, including the key document "Classification of Chemicals in the Brussels Nomenclature 1958".

Funds for Research and Development in Industry in the United States

A survey, *Funds for Research and Development in Industry, 1957 : Performance and Financing*, made for the National Science Foundation by the Department of Commerce, Bureau of the Census, is the first in a series of annual surveys to be conducted in the United States by that Bureau for the Foundation (Surveys of Science Resources Series. Pp. xiv+119. Washington, D.C.: Government Printing Office, 1960. 65 cents). More than half the total 7,200 million dollars was for research and development in the aircraft and electrical equipment industries, and 52 per cent of such work was financed by the Federal Government ; 241 million dollars was for basic research ; 1,514 million dollars for applied research ; and 5,401 million dollars for development. Of the total, 6,060 million dollars was expended by companies employing 5,000 or more persons. Chemical and allied products ; stone, clay and glass products; petroleum refining and extraction; and primary metals financed 90 per cent or more of their research and development. The average cost per scientist and engineer in research and development was 34,300 dollars, varying from 20,200 dollars in food and kindred products to 42,300 dollars in aircraft, and from 20,400 dollars in companies with fewer than 1,000 employees to 37,400 dollars in companies with 5,000 or more. Wages and salaries averaged 51 per cent of research and development costs in 1957, ranging from 46 per cent in the electrical equipment industry to 67 per cent in the paper and allied products. Company-financed research and development (excluding that federally financed) averaged 1·6 per cent of net sales, and varied widely from less than 1 per cent in food and kindred products, paper and allied products, petroleum refining and extraction, and primary metals, to 6 per cent in scientific and mechanical measuring instruments; but including federally financed research and development the average was 3·3 per cent of net sales.

Employment of Librarians in the United Kingdom

The recent annual report of the Manchester Public Libraries Committee referred to difficulties which were being experienced through the rapid turnover of staff and the progressive weakening of professional experience. The Library Association has been increasingly disturbed in recent years by the extent to which it has been necessary for public libraries to fill professional posts with partly qualified staff; whereas in 1957 only 16 per cent of administrative, professional and technical posts were occupied by unqualified staff, in 1960 it had risen to 27 per cent, and at the end of 1960, out of a total of 2,738 posts, 277 were vacant and 998 occupied by unqualified staff. This situation led the Library Association to seek information from 484 public libraries regarding their turnover of staff since January 1959, and replies received from 352 showed that 47 per cent of qualified staff leaving were lost to the service, only 56 per cent of the vacated posts were filled by qualified librarians and 10 per cent remained unfilled. There was a loss of 299 qualified librarians to other types of library and public employment.

These and other figures were quoted by Mr. A. Fitch, who raised the subject in an adjournment debate in the House of Commons on March 1 and referred to the estimate in the Roberts report that an increase of more than 2,000 qualified librarians in the public library service was required for an efficient service. He suggested that the shortage was to be attributed to the unsatisfactory salary scales, and that the recommendations of the Roberts Committee were being ignored by the library authorities. In replying on the debate, the Parliamentary Secretary to the Ministry of Education, Mr. K. Thompson, referred to the Minister's announcement on December 15 that it was the Government's intention that the Minister of Education should have general responsibility for the supervision of the public library service, and that after certain preliminary work had been completed legislation would be laid before the House. Mr. Thompson said that this preparatory work was actively proceeding and broad measures of agreement already existed on many of the problems. Whatever new duties might be laid on the Minister of Education, the library service would continue to be an essentially local authority service, with Ministerial intervention limited to the minimum consistent with ensuring the maintenance of uniformly high standards. The Government accepted the view of the Roberts Committee that standards of staffing should be high both in numbers and quality, but he insisted that salary scales and conditions of service must be negotiated between librarians and the authorities employing them and that the Minister had neither the power nor the duty to intervene. As regards wastage of staff, Mr. Thompson thought that in so far as this applies to staffing of libraries elsewhere it might be to the advantage of the library system as a whole and encourage inter-library co-operation.

Abstracts of Human Developmental Biology

Excerpta Medica has issued the first of a new monthly journal called *Abstracts of Human Developmental Biology* (1, No. 1; January 1961. Pp. 52. Abstracts No. 1–164. Published monthly. Amsterdam and London: Excerpta Medica Foundation, 1961. Subscription rate: £6 18*s*. per annum). The new journal covers the experimental and clinical aspects of normal and pathological human development, including fundamental aspects of general morphogenesis, of reproduction, of transplantation in post-natal life, and of pathological growth, as compared with normal development, differentiation and growth. The new journal, developed and published with the aid of a grant from the United States Public Health Service, will contain approximately 2,000 abstracts a year, and will include classified subject and author indexes. It will thereby contribute to collaboration between specialists in the field of obstetrics, surgery, pædiatrics, social medicine, embryology, experimental teratology, genetics and immunology, by integrating information in all these disciplines so far as they concern the problems of normal and abnormal development, reproduction and transplantation.

Florida State Museum, University of Florida

The Director's report for 1959–60 of the Florida State Museum, University of Florida, has recently become available (Pp. 19+2 plates. Gainesville, Fla.: University of Florida, Florida State Museum, 1960). This Museum, which serves the people of the State and the University community in particular, is much hampered by lack of space and also of staff. The Department of Exhibits operates in three distinct areas of service. New exhibits are produced and loan exhibits are scheduled for the halls in the headquarters museum, a major reconditioning operation to modernize the archaic exhibits in the Seagle Building is in progress, and its influence also works in the aptly named 'out-reach exhibits'. Among the special exhibits are "You and the Atom", which illustrates the basic principles of nuclear energy and peace-time applications in medicine, agriculture and industry.

Control of Red Scale in Citrus Fruit

Red scale is the most important insect pest of citrus fruit in Australia. Standard control methods involving oil sprays or fumigation with hydrocyanic acid are by no means satisfactory. Mr. B. H. Martin and Dr. R. F. Black, of the Griffith Irrigation Research Station, have studied the possibilities of heat treatment as a control measure. An essential feature of any such treatment is that it will kill the scale without damaging the tree or the fruit. The experiments have been described in a recent issue of *Rural Research* (23, Sept. 1960). The technique used in the experiments consisted of heating scale-infested fruit in ovens at different temperatures and for different periods of time. The effect of heat on fruit was therefore examined but not the possible damage to trees. It was found that all the scales could be killed by a temperature of 70° C. maintained for 1 hr. This treatment, however, resulted in severe damage to the fruit. Equally effective 'kills' were obtained at a temperature of 50° C. kept up for 2½ hr. During this treatment the fruit was not damaged. Increasing the humidity during the 50° C. treatment did not alter the time necessary to kill the scale, and it is apparent that high temperature rather than dehydration was the direct cause of death. Further experiments have involved treating the trees themselves. The technique used was to enclose the trees in plastic sheets and utilize solar energy as the heat supply. Some difficulty has been experienced in maintaining temperatures at a safe level.

Congelifraction of Clays

THE clay fraction of soils is customarily regarded as a product chiefly of chemical rather than mechanical processes. While chemical alteration is undoubtedly necessary to produce clay minerals in the first place from the components of crystalline rocks, it now seems that at least one form of mechanical weathering, namely, congelifraction, can be effective in reducing particle size well down into the clay grade in unconsolidated sediments. I. C. McDowall (*N.Z. J. Geol. and Geophys.*, **3**, 337 ; 1960) has investigated the effects of alternate freezing and thawing on water-saturated samples of kaolinite, vermiculite, halloysite, and weathered clays containing illite and halloysite. The particle size distributions were determined at intervals by the Andreason pipette method, and it was found that appreciable reduction of particle size occurred during 800 cycles. The process appears to operate on particles at least as small as 1μ, and is most rapid in those minerals where the bonding between the basal planes of component sheets of the clay mineral is weakest. In cold climates the process might therefore be an important one in the formation of plastic clays, perhaps particularly of fireclays.

Navigation down the Centuries

A SHORT review of navigational methods from the earliest times to the present, with special emphasis on the newest techniques with Earth satellites, is made in a 24-page publication of the Coast and Geodetic Survey of the United States Department of Commerce, entitled *Use of Artificial Satellites for Navigation and Oceanographic Surveys*, by Paul D. Thomas (Technical Bulletin No. 12. Pp. i+24. Washington, D.C.: Government Printing Office, 1960. 25 cents). The first half of the publication is a historical review, beginning with Hipparchus and Ptolemy, touching on Galileo, the French expeditions of the seventeenth and eighteenth centuries, and the development of the marine chronometer, before coming to radar systems, *Loran* and inertia navigation. The second half of the paper is devoted to Earth satellites. Here the main interest is in the transit system of satellites, already in action on an experimental basis, from which position can be obtained by interpretation of the Doppler shifts of the radio-waves received from the satellites.

Use of Superconductors for producing Strong Magnetic Fields

THE production of strong magnetic fields by the use of superconductivity phenomena would appear to be considerably advanced by the development of a new superconducting compound of niobium and tin, Nb_3Sn, by the Bell Telephone Laboratories. The distinctive property of this material is its ability to retain superconducting properties even when exposed to fields of about 90,000 oersteds, and possibly even higher, while carrying currents of approximately 100,000 amp. $cm.^{-2}$ (see Kunzler *et al.*, *Phys. Rev. Letters* for February 1, 1961). The new material is very brittle, but by packing a narrow niobium tube with appropriate quantities of powdered niobium and tin, sealing the ends of the tube with niobium plugs, reducing the tube by swaging and drawing it, a wire of 0·015 in. diameter which can be wound into a solenoid coil is formed. On heating the wire to about 1,000° C., the inner materials react to form Nb_3Sn, and the necessary superconducting properties are developed. Owing to mechanical difficulties associated with the substance at high fields, a large solenoid of the material has not yet been wound, but it is anticipated that these difficulties will be overcome within the next twelve months.

The Iron and Steel Institute, the Institute of Metals and the Institution of Metallurgists

THE Councils of the Iron and Steel Institute, the Institute of Metals and the Institution of Metallurgists have recently examined the problems of closer co-operation between these three societies. After careful consideration they have concluded that amalgamation of the three societies would not be practicable within the foreseeable future. The three Councils, therefore, decided to set up a permanent Joint Consultative Committee of the three societies, which will meet regularly and advise their Councils on all activities and questions of common interest.

Lederle Medical Student Research Fellowships

THE Lederle Laboratories Division of the American Cyanamid Co. announces that it is making available fellowships to medical schools throughout the United States and Canada for the year 1961. These fellowships, in amounts not exceeding 600 dollars a year for any one individual, are intended to relieve in part the financial burden of students who desire to devote their summer vacations to research in the preclinical departments. Students who apply for Lederle Medical Student Research Fellowships must have the consent of the faculty member under whose supervision their research is to be conducted. Further information can be obtained from the Lederle Laboratories, American Cyanamid Co., Pearl River, New York.

Carlsberg–Wellcome Travelling Research Fellowships, 1961–62

APPLICATIONS are invited for the Carlsberg–Wellcome travelling research fellowships, 1961–62, the object of which is to encourage co-operation, on an exchange basis, between Danish and British research workers in any branch of the natural sciences which has a bearing on human and animal medicine. One fellowship annually is awarded to a candidate from the United Kingdom for a year's work in Denmark and one annually to a Danish candidate for a year's work in the United Kingdom. The stipend may range from £900 to £1,300 per annum (or the equivalent sums in Danish kroner), travelling and some incidental expenses being provided in addition. The tenure of the awards will start in September 1961. Further information can be obtained from the Assistant Scientific Secretary of the Wellcome Trust, 52 Queen Anne Street, London, W.1. Applications must be submitted before April 30.

Medical Research Fund for Australia and New Zealand

A FUND has been established by the Life Offices' Association for Australasia to promote and assist scientific and medical research. For the present it is intended to use the resources of the Fund to stimulate and support research in the field of cardiovascular function and disease. Grants from the Fund will be made as follows: *grants in aid*, which will be given to non-profit institutions with basic facilities and qualified personnel for medical research, and will range from £1,000 to £3,000; *research fellowships*, which will be open to medical graduates or those with equivalent scientific training, and will fall into two categories: (*a*) fellowships taken up in Australia and New Zealand for a period of one year (£2,200–£2,500 p.a.); (*b*) travelling fellowships, for a period of two years abroad, followed by a third year in an approved institution in Australia or New Zealand (£2,500–£3,000 p.a.). Further information and application forms can be obtained from Dr. H. M. Whyte, Life Insurance Medical Research Fund of Australia and New Zealand, 87 Pitt Street, Sydney. Applications for all awards must be received by July 1.

André Mayer Food and Agriculture Fellowships

THE Food and Agriculture Organization of the United Nations has announced that it will offer ten or twelve André Mayer fellowships in 1961. These awards will be made under the following two groups: *research*, for unusually promising persons with research experience behind them who would offer a guarantee for the carrying out of independent research work; *research training*, for younger and promising individuals who have demonstrated an inclination towards, and an aptitude for, research work. Due consideration will be given to geographical distribution, to ensure that a proportion of the awards is given to candidates from countries where research facilities are not highly developed and the need for trained research workers is great. The subjects presented must be in relation to the Organization's activities, which comprise: land and water development, plant production and protection, animal production and health, rural institutions and services, fisheries, forestry and forest products, nutrition (non-medical), atomic energy in food and agriculture, agricultural economics (commodities, statistics, economic analysis). Further information can be obtained from the National Committee for the United Kingdom of the Food and Agriculture Organization, Ministry of Agriculture, Fisheries and Food, Whitehall Place (East Block), London, S.W.1. The closing date for application is April 30.

University News: Birmingham

THE following appointments have been announced: Dr. M. Z. Atassi, to be Research Fellow in the Department of Chemistry; Dr. B. Cockayne, at present Research Fellow in the Department of Physical Metallurgy, to be lecturer in the Department of Physical Metallurgy; M. J. Hamlin, to be lecturer in the Department of Civil Engineering; Dr. D. A. Smith, to be lecturer in the Department of Microbiology. The title of reader in neuropharmacology has been conferred on Dr. P. B. Bradley, senior lecturer in electrophysiology in the Department of Experimental Psychiatry.

Edinburgh

DR. DUGALD GARDNER has been appointed as senior lecturer in pathology. Dr. R. C. Dorf has been appointed as a lecturer in electrical engineering, and T. Astarabadi as a lecturer in physiology.

Announcements

DR. C. J. JACKSON has been appointed chairman of the Water Pollution Research Board for the period April 1, 1961–March 31, 1966, in succession to Dr. F. H. Garner, who completed his term of office on March 31. Dr. Jackson is in charge of all water pollution problems for the Distillers Co., Ltd., both on the potable and industrial sides.

PROF. J. A. GOEDKOOP has been appointed managing director for research at the Reactor Centrum Nederland, where he was previously in charge of the Physics Department. Prof. Goedkoop has been at the Centrum since its foundation in 1955. For some years he directed the physics research at the Norwegian–Netherlands Joint Establishment for Nuclear Energy Research (JENER) at Kjeller, Norway. He is also a part-time professor at the Leyden State University.

A JOINT meeting of the Challenger Society and representatives from the Marine Laboratories (Development Commissioners' Scheme) will be held at the Royal Dublin Society, Ballsbridge, Dublin, during May 24–25. Further information can be obtained from the Challenger Society, c/o Dr. A. E. J. Went, Fisheries Division, Department of Lands, 3 Cathal Brugha Street, Dublin.

THE Nutrition Society (Scottish Group) is holding a symposium on "The Relative Values of Animal and Vegetable Fats in Nutrition" at the Physiology Lecture Theatre, Queen's College, Dundee, on April 22. Further information can be obtained from the honorary secretary of the Scottish Group of the Nutrition Society, Dr. J. Davidson, Rowett Research Institute, Bucksburn, Aberdeen.

THE annual general meeting of the Oil and Fats Group of the Society of Chemical Industry is to be held at Liverpool on April 25. It will include an address by Dr. A. T. James, of the National Institute for Medical Research, on "Applications of Gas Chromatography to Some Medical Problems". Further information can be obtained from Dr. H. Jasperson, c/o J. Bibby and Sons, Ltd., Research Department, King Edward Street, Liverpool 3.

ERRATA. Two mistakes in the list of new Fell
of the Royal Society of Edinburgh (*Nature*, Marc
p. 876) have been pointed out: Dr. K. B. Fr
senior lecturer in bacteriology (not botany)
University of Aberdeen; and the name of D
Gimingham, senior lecturer in botany in th
sity of Aberdeen, was omitted.

AFFORESTATION OF UPLAND HEATHS

FORESTRY Commission *Bulletin* No. 32 purports to deal with what are termed 'upland heaths', which are said to occur along the eastern side of Scotland and northern England, and to be distinguishable from lowland heaths formed farther south*. They are distinct from the peat-covered lands in the western parts of the country, which were the subject of an earlier *Bulletin*—No. 22—by the same author, entitled: *Experiments in Tree Planting on Peat* (H.M. Stationery Office, 1954). It reviews experimental work carried out over a period of thirty-six years during 1921–57, and records all that was attempted by the Forestry Commission, "with an assessment of the results so far".

The last phrase gives the clue to one of the major obstacles which research workers encounter when they undertake experiments on a field scale with the view of improving sylvicultural and management techniques. It is not possible to bring such experiments to a conclusion within less than a century, especially when they are conducted on such infertile sites as the degraded forest soils of early centuries, now covered with ericaceous vegetation, which go by the name of heaths. These soils, it is now generally accepted, have arisen as a result of forest destruction in the past, and of repeated burnings and heavy grazing which have killed off the woody vegetation. Whatever the original composition and structure of the former forest soils may have been, these have been lost, and the problem of the restoration of the soils to their original relatively fertile state is immense.

Since these heath sites are almost entirely unproductive from an agricultural point of view and should never have been deforested, it is only right and proper that they should, if possible, be reforested; and it is not to be wondered at that the Forestry Commission has acquired, and continues to acquire, extensive areas of such 'marginal' land, and rightly so.

The length of time which this kind of study requires has another important effect, namely, that no one individual can commence the work and bring it to completion in his life-time. If he could, it is more than likely that by the time he reached the end of his span he would have forgotten what the conditions were when he began his experiments. In these experiments no fewer than eight senior officers and three junior officers are credited with having played an important part, not counting the author himself. The difficulty of seeing the work as a whole and in its proper perspective is increased by so many changes over such a relatively short time. Another embarrassment to the forest research worker is that, no sooner do his experiments begin to indicate apparent success, than the inexperienced general practitioner draws his own conclusions and immediately applies a new method before it has been tested thoroughly. The older forester is more wary.

This particular experimental project was begun in 1921, and the major experimental areas were at first concentrated in six forests, four in Scotland, and two in the north of England. Later on experimental work was extended on a less-intensive scale to other forests. The kinds of experiment attempted were many, too many to be handled adequately, but the principal projects dealt with were: methods of ground preparation; various kinds of ploughing; trials of species; use of manures at time of planting; and later, use of nurse trees and mixtures of species, besides a variety of miscellaneous procedures. The result of all this was an accumulation of a vast amount of mensurational and other data. The earlier experiments were somewhat crudely set out, but later widespread use was made of approved methods of layout and of statistical methods of handling the results. Mr. Zehetmayr is to be congratulated on having presented his information in a very readable form and on treating the problem with admirable judgment. The *Bulletin* contains a mass of information on method and species. The conclusions are presented in an excellent summary, and it must be said that they do not differ essentially from those reached by tree-planters in Britain long before the Forestry Commission was born, except in respect of the newer species. The early work of the Commission was bedevilled by an idea that spruces, because they are highly productive on suitable sites, should be grown everywhere, even on upland heaths. Another herring drawn across the trail was the idea, imposed from above, that the deeper one ploughed the better. The unjustifiable opinion was held, and often still is, that the trees could be compelled to extend their roots down into the execrable material on which the heath grows. Fortunately, the experiments indicate that it is more effective to prepare the surface-layer than to bring up a mass of inert mineral matter, containing a small proportion of soluble minerals, which in time return to the depths whence they came. On sites with richer sub-soils nearer the surface, deep ploughing seems to be more useful—at least for a time. There is an undoubted stimulus to tree growth on ploughed land due to improved mineralization of the organic matter, but how long it continues remains to be seen. It is claimed that ploughing has extended the area on which planting is economically possible and has improved growth on moderately fertile areas. The possibility of future troubles is not overlooked.

It is interesting to find that the author believes, and rightly, that for these upland heaths, Scots pine will remain the most important tree. Corsican pine and Japanese larch—more exacting trees—do not seem to be suitable substitutes, but the shore or lodgepole pine from North America is a promising introduction.

This publication, like certain others produced by the Forestry Commission, can be criticized on a number of points. In the first place, some attempt should have been made to use the classification of heath-types dealt with in Chapter 1, and to treat them by classes. For example, upland heaths on the Red Sandstone areas of Scotland are radically different from those on the Jurassic of the Cleveland

---

* Forestry Commission. *Bulletin* No. 32: *Afforestation of Upland Heaths*. By J. W. L. Zehetmayr. Pp. v+145+34 plates. (London, H.M. Stationery Office, 1960.) 17*s*. 6*d*. net.

Hills of Yorkshire. The so-called 'pans' differ markedly, depending on the looseness of texture of the underlying glacial deposits. The essential difference between the upland heaths of Britain and the continental heaths of Denmark, Germany and the Netherlands is clearly explained in Chapter 2. While such differences may justify the adoption of a completely independent attitude in Britain they do not excuse the neglect of the important work done in France by Duchaufour on heath soils or by Scandinavian, other than Danish, workers. Nor is the ignoring of the heath afforestation carried out in Great Britain long before the Forestry Commission was constituted excusable. Whether Continental heaths have "a longer history of systematic afforestation than our own" depends on what is meant by 'systematic'. The skilled tree-planters of Britain, in the eighteenth and nineteenth centuries, with a life-time of experience behind them, came to very definite conclusions about suitability of species, the value of ploughing and other techniques, and in forestry a life-time of experience in one locality may compensate for lack of intensive experiment at heavy cost, and the use of statistical methods to support the very obvious results which the intelligent observer sees and records in his memory, if not in his note-book. This is possibly rank heresy, but when one is confronted with the meagre conclusions from thirty-six years of intensive experiments, involving a multitude of measurements and calculations, one may be permitted to wonder if the capacity of the human brain is not nowadays underestimated.

Mr. Zehetmayr deserves great credit for the immense pains which he has taken to range over space, at least, and make himself conversant with heath-land planting. He has dealt with the enormous accumulation of experimental data in a masterly manner and makes good use of figures and illustrations. As a result of his breadth of vision, his conclusions are sound and are devoid of the exaggeration and puerile propaganda which sometimes detract from the value of forestry technical publications. He also places the important work so far achieved in its correct perspective historically, although perhaps his glance has been directed too far ahead and not enough backwards. Much more intensive soil research, as opposed to more-or-less empirical experimentation, is now required if further real progress is to be made. Meanwhile, adopting the same cautious attitude as the author, foresters and tree-planters would do well to be conservative, rather than rash, in their attitude, and to eschew the high-living tree species in favour of the abstemious. They should read and apply the lessons so far learned with discrimination, paying special heed to variation in locality conditions. In particular, deep ploughing on a large scale should not be used indiscriminately; it is often not only unnecessary but also harmful, especially in its effect on the drainage of catchment areas. The dweller in the lowlands is often unaware of what is happening in the uplands in these days. The excellence of Mr. Zehetmayr's interpretation will give great satisfaction to all who have participated in this project.

M. L. ANDERSON

REORGANIZATION OF BRITISH NATIONALIZED TRANSPORT UNDERTAKINGS

NEITHER in the White Paper on the *Reorganization of the Nationalized Transport Undertakings** nor in the debate on January 30, in which the Minister of Transport, Mr. E. Marples, asked the House of Commons to take note of the proposals for reorganization, was any reference made to the importance of research or of a sufficiency of scientific and technical man-power in Britain. Furthermore, the organization chart appended to the White Paper gives no indication as to how the organization for research is affected. The White Paper puts as the Government's aim undertakings soundly based on organization and finance, providing efficient services and giving a good livelihood and worth-while jobs to those who work in them. It directs attention to the fact that the railways are a vital basic industry, employing 500,000 people and representing an investment of nearly £1,600 million, still growing by more than £100 million each year. A railway system of the right size is regarded as an essential element in the British transport network, and will remain so for as long as can be foreseen, but the White Paper does not discuss the vital question: What is the right size? The related question of congestion on the roads is ignored, and while the idea of the railways as a social service is rejected, the question of uneconomic services such as branch lines is reserved for further consideration; it is merely stated that for the time being railway losses on any such services will be covered by the contributions proposed from public funds.

This point was stressed during the debate by Sir Toby Low, chairman of the Select Committee on Nationalized Industries, who, while agreeing that, in the main, the Government's proposals were in line with the recommendations of the Select Committee, was doubtful whether full control over the finances of the railway system could be achieved until the problem of dealing with uneconomical services had been decided. Sir Toby insisted that we could find out why losses are incurred, and he urged in conclusion that the real problem was not money but morale. Success can only be achieved by the vigorous use of every instrument of management and of science. Apart, however, from the Minister's announcement that the Government had decided that the main-line electrification scheme from Euston to Crewe, Manchester and Liverpool should go ahead as quickly as was consistent with the best use of the available resources, nothing in the debate clarified the uncertainty about the progress of modernization or the future of the uneconomical services. The Joint Parliamentary Secretary to the Ministry of Transport, Mr. John Hay, did not accept Sir Toby Low's challenge, and only stated that in 1960 the Treasury provided £160 million and in 1961 £140 million for investment in the railway industry, as a result of which more than seventy major projects had already been approved. Earlier, Mr. Marples had said that he would have to keep the electrification scheme (which is to cost £175 million) under close review to see how the estimates of cost and the rate of working compared, but that this did not necessarily mean that no other major main-line electrification scheme would be approved.

---

* Ministry of Transport. *Reorganization of the Nationalized Transport Undertakings.* Pp. 14. (Cmnd. 1248.) (London: H.M. Stationery Office, 1960.) 1*s.* net.

The White Paper states that the main conclusions reached by the Government are that the activities of the British Transport Commission, as at present constituted, are so large and diverse that it is virtually impossible to run them effectively as a single undertaking. There has been confusion in judging between what is economically right and what is socially desirable, and the commercial capability of the railways is circumscribed by outmoded statutory obligations and restrictions on their trading operations. Mounting deficits (now totalling £500 million), the size of capital debt in relation to the earning capacity of the assets and the increasing burden of interest (already some £75 million alone) as modernization proceeds, present a situation detrimental to the morale of management and workers, to financial control and to hope of recovery. Accordingly, the Government has decided to replace the British Transport Commission and the existing organization by a new structure designed to overcome the main defects and disadvantages of the present organization, to reconstruct the finances of the Commission, and of the railways in particular, and to give the various undertakings the maximum practicable freedom of operation in their commercial affairs.

In the new structure, each of the main activities of the present Transport Commission—railways, London Transport, docks, inland waterways—will be managed by a separate Board holding its own assets and responsible for its own capital debt. The British Railway Board will be responsible for running the railways as an effective national system, but will perform only those central functions which are essential to the running of the railways as a single entity, including policies for safety, training and research, and the determination of the future size and shape of the railway system ; all other functions will be the responsibility of the Regional Railway Boards. Co-ordination of policy between the new Boards for railways, London Transport, docks and inland waterways will be the responsibility of the Minister of Transport, assisted by a new Nationalized Transport Advisory Council. His special duties in respect of safety, training and research will continue. As regards finance, the Government proposes to write off £400 million of the £2,000 million capital liabilities of the British Transport Commission, and when £400 million of the remainder has been transferred to the appropriate new Boards, to place in suspense £800 million of the £1,200 million still remaining against the railways so that it carries neither fixed interest nor fixed repayment obligations. The amount and treatment of this suspense account will be subject to review from time to time in the light of developments. It is expected that the railways will eliminate their present operating loss of £60 million a year. The importance of efficient operation and the most economic use of man-power is also emphasized, and the railways are to be freed from statutory control over their charges except for fares in the London Passenger Transport Area.

THE AGADIR EARTHQUAKE

FOLLOWING a detailed local study of the Agadir earthquake of February 29, 1960, P. Erimesco has published the conclusions in the *Bulletin de L'Institut des Pêches Maritimes du Maroc* (No. 5 ; September 1960). The author states that earth tremors in Morocco are not infrequent, although they very seldom attain an intensity of more than 5 on the Mercalli scale. In the list given in the text for the period from May 31, 1934, to October 28, 1951, eighteen earthquakes have intensity 4 or greater. Two of these were of intensity 7, and four had maximum intensity 6. The town of Agadir is situated at the intersection of two lines of marked seismicity. One line follows the region between the High Atlas Mountains and the Anti Atlas. The other crosses the High Atlas Range and continues to the coast of the Mediterranean.

During the night of February 29, 1960, after two slight tremors, an earthquake of unusually high intensity for the region (IX–X) devastated the town of Agadir (initial time 23h. 40m. 12s. G.M.T.). According to the map produced by the author, showing isoseismal lines for the shock, the small region of greatest intensity inside isoseismal X lies just on shore. The local estimate of depth of focus lies between 3 and 7 km., and of the magnitude of the shock 5·75 to 6. According to Vít Kárník, of Czechoslovakia, the average formula connecting magnitude (M), intensity (I_0) at epicentre, and depth of focus (h) for European shocks is :

$$M = 0{\cdot}67\, I_0 + 1{\cdot}7 \log h - 1{\cdot}4$$

For $I_0 = 10$ and $h = 5$ km. this gives $M = 6{\cdot}48$, which is somewhat higher than the local estimate.

Whole areas of the town, situated near the port and along the shore, suffered very heavy damage, and in certain places total destruction. A squadron of the French Navy, rushing help to the stricken town, registered on the way two hitherto unknown depths of 15 m. and 10 m. where charts indicated 900 m. and 90 m., respectively. To check these soundings taken visually, two vessels of the Navy made, the next day, a systematic search. At the places in question, no echo at all could be obtained.

At the moment of the earthquake, the trawler *Rolando*, heading south-west, passed approximately the place where later the 10-m. depth was observed. The crew reported that they felt three shocks, as if their boat had hit a solid object. The sea became very choppy for several minutes and a glow appeared in the sea, shifting rapidly towards the town of Agadir. Shortly afterwards they saw the lights in the town going out.

In spite of near-by badly damaged buildings, the quay walls were found practically without serious deformation, with the exception of two short oil wharfs. The slip for the fishing boats had not suffered at all. The tide gauge at the time of the earthquake registered the choppy sea in the harbour usual during that time of the year on account of wind from the south-west, but no exceptional waves. To investigate changes on the sea-floor consequent on the earthquake, P. Erimesco with his assistants examined the effects in the harbour of Agadir and along the shore. In the Bay of Agadir, systematic soundings were made and samples were taken from the bottom at the place where the 10-m. depth was observed. The soundings could not detect any variation from the depths marked on the charts; and the bottom samples at the place where volcanic activity had been suspected contained living annelids in perfect condition.

Thus, contrary to local reports at the time of the earthquake, we have evidence of a most unusual occurrence, namely, an area of intense earthquake destruction practically on the shore line, and virtually no effect at sea—neither the sea bottom nor the sea waves—except perhaps the rising of a shoal of zooplankton and a cloud of mud in the sea.

P. Erimesco seeks to explain this by reference to the local geology. He states that from the geological structure of the region it can be inferred that the almost vertical Cretaceous and Tertiary strata near the coast are dipping steeply underneath the sea bed. The covering Quaternary and Recent layers are sub-horizontal or horizontal and, in their upper part, not yet compacted, and are saturated with water. Earthquake waves in the Cretaceous, or in the underlying folded Palæozoic strata, are thus propagated mainly in the solid rock, and, by total reflexion, literally channelled towards the outcrop of these strata on the coast. In the unconsolidated and water-saturated material at the bottom of the sea, the energy of the shock waves is largely dissipated in the material, and only locally can a fraction of the energy released by the earthquake reach the surface of the sea. The trawler *Rolando* might have been at just such a place.

E. TILLOTSON

SEDIMENTATION IN OROGENIC BELTS

A LITTLE more than twelve years ago, Kuenen and Migliorini set out the evidence which had led them independently to the fruitful idea that certain marine sediments may be re-deposited in deeper water, possibly many hundreds of kilometres distant from their temporary resting places, by the action of turbidity currents. The speakers at the symposium "Some Aspects of Sedimentation in Orogenic Belts", held by the Geological Society at the Royal Institution on February 8, had a wide field over which to range, but it was remarkable how much of the work described stemmed directly or indirectly from this concept.

In opening the symposium the president, Prof. S. E. Hollingworth, reminded the audience how present-day views on re-sedimentation could be traced back to the work of Bailey and O. T. Jones in the 'thirties. The principal speakers in the first session dealt with work in the Alps (Prof. R. Trümpy), the Polish Carpathians (Prof. M. Ksiazkiewicz) and the Himalayas (Prof. W. D. Gill). In the second session Prof. A. Wood spoke on the Lower Palæozoic of Wales, Prof. Scott Simpson on the Upper Palæozoic of south-west England, Prof. R. M. Shackleton on the Dalradians and Prof. Gill on a Carboniferous basin in Ireland. Discussion followed in each session. A summary account will appear in the *Proceedings of the Geological Society*, and rather than duplicate this summary I propose to consider in a more general way some of the topics which came up during the meeting.

Prof. Trümpy, who has recently provided a welcome account of alpine sedimentation[2], opened with a warning note on the use of the term 'flysch'[1,2], which, he said, describes a facies group and not a rock. Flysch, he continued, is marine, thick (> several 100 m.), and essentially composed of sandstones and shales in proportions varying from about 5 : 1 to 1 : 10. Individual beds can be followed for long distances, and flysch is in general monotonous. The shales are silty and the sandstones are often felspathic and generally micaceous. True greywackes are rare. Breccias and conglomerates, though quite subordinate, are typical of many flysch deposits. Prof. Trümpy pointed out that graded calcarenites are not called flysch in the Alps.

The structural setting in which flysch appears was discussed by several speakers. Prof. M. Ksiazkiewicz[3-9] showed how flysch was deposited in various parts of the Carpathian basin at different stages of its evolution. Thus in the outer zone folded in the Lower Miocene the flysch formed from the end of the Jurassic without interruption until the Oligocene. In the middle zone flysch did not appear until the Lower Senonian shortly before the pre-Maestrichtian orogenic stage, while in the inner zone flysch rests on rocks folded at the end of the Cretaceous. In the Alps, Prof. Trümpy suggested, flysch marked a stage when tension gave way to compression. Prof. Scott Simpson made the point that flysch is not confined to fold belts, while Prof. Gill gave a striking account of a comparatively small and shallow epicontinental basin in the Visean of County Dublin, in which slides and turbidity currents had developed in a non-orogenic setting.

The difficult question of the depth of water overlying flysch deposits was approached in several ways. Prof. Trümpy placed the fossils of the Alpine flysch in three ecological groups; an authochthonous fauna of fossils such as fucoids and helminthoids derived from soft-bodied animals indicating deep water beyond the penetration of light; a transported benthonic fauna including the larger foraminifera, calcareous algae and bryozoa, preserved in graded sandstone beds; and thirdly, pelagic microfossils such as globigerinids and radiolaria. Dr. J. F. M. de Raaf reported that foraminifera similar to or identical with recent deeper water species had been found in pelitic rocks above individual turbidites from flysch deposits in Switzerland, France, Spain, Italy and Greece. Profs. Ksiazkiewicz, Scott Simpson and Trümpy gave evidence which indicated that deep-water conditions were established before deposition of flysch began. Where shallow-water sediments were followed by flysch an intervening group of deep-water sediments was often present. In this connexion an interesting parallel emerged between a succession from south-west England in which, during the Variscan orogeny, Upper Devonian shallow water sediments were followed first by deep-water shales, cherts and limestones and then by Namurian flysch, and certain Alpine successions in which shallow-water platform deposits were covered first by shales and fine-grained limestones with a purely pelagic microfauna and then by flysch. In both regions the arrival of flysch was heralded by a phase when sedimentation did not keep pace with downwarping. In contrast, Gill attributed the lack of flysch over the greater part of the Himalayas to the building up of land masses in Middle and Upper Eocene time.

Prof. A. Wood[10–12] described some of the variations in lithology shown by the Aberystwyth grits which he employed to demonstrate the changes which could occur in turbidites as they are followed down-current. He discussed the behaviour of the associated mudstone and suggested that under certain conditions muds were stripped off and added to the turbid suspension passing overhead. Detailed work of this nature and of the kind carried out by Radomski in the Alps is beginning to establish the relationship between changes in facies and the several environments which might be expected in a single basin and seems likely to improve our understanding of the mechanism of turbidity currents.

Later in the discussion Mr. W. A. Cummins suggested that the finer-grained chloritic fraction of some greywackes might in part be a secondary feature. The apparent lack of contemporary greywackes might be explained in this way. Dr. J. G. Ramsay and Dr. J. L. Knill mentioned the difficulties which may arise in establishing the original attitudes of deformed sedimentary structures. Although, as Prof. Wood pointed out, account is usually taken of the effects of plunging structures, so far as I am aware the effects of shear folding in which the angle between a sedimentary structure and the fold axis alters during folding have not been considered. The results presented by Ramsay[16] on this question should allow observations to be made in rocks deformed in this way.

Prof. Shackleton summarized present knowledge of Dalradian current directions[13–15], and commented on the distribution of the various Dalradian sediments, some of which remain remarkably consistent from western Ireland to north-east Scotland. Dr. B. Sturt described variations within the Dalradian of Perthshire and Prof. Shackleton mentioned the recent recognition of turbidites near the base of the Torridonian succession in Colonsay and Islay.

One of the most arresting features of the symposium was the sequence of maps presented by Prof. M. Ksiazkiewicz[3–9], which illustrated the results of measurements of current directions and facies analyses in the Polish part of the Carpathian flysch zone. This work, carried out by Prof. Ksiazkiewicz and S. Dzulynski, A. Slaczka, K. Zytko, W. Sikora, L. Koszarski and A. Radomski, has resulted in an elegant demonstration of the forms of the troughs and of the whereabouts and nature of the source areas. The varying directions taken by sediments were shown, and it was demonstrated, for example, that for a considerable time the axes of two neighbouring troughs sloped in opposite directions so that a northern trough was fed from the west and a southern from the east. These important results provide one of the most detailed accounts yet established of the movement of sediment within an evolving orogenic belt. I suggested, when summing up the day's discussion at the close of the meeting, that a synoptic account of comparable observations made in the British Palæozoic might be useful in bringing out what is known on this topic and what we need to find out in the future.

ROCK ENGRAVINGS IN NORTHERN ITALY

SOME years before the First World War, l'Institut de Paléontologie Humaine was founded by Albert I, Prince of Monaco. Its various publications, not least the series of *Archives*, are of importance to every prehistorian. *Memoire* 31, entitled *Le Grande Roche de Naquane*, has maintained the standard. Rock engravings in the Val Camonica have long been known, especially as the result of the publications of G. Marro and R. Battaglia, but the time was ripe for this detailed study by M. Anati to appear. The carvings are found on rocks, many hundreds of them, up the valley for about 30 miles from near Boario to Edolo. A line drawn on a map from Bergamo to Bolzano will pass not far from the art complex. The author has attempted to separate these stylized drawings into three series: the first dating may be as old as the late Bronze Age, a second belonging to the Iron Age, and a third, which was still being made when Rome conquered northern Italy. A glance at the illustrations—there are no less than 52 full pages—reveals that there are depicted in a pocking technique animals, mainly domestic but including stags, human beings and various weapons and signs. The author decided not to select his illustrations from various sites in the complex, but to concentrate on a single rock surface. There is thus given a complete account of at least one locality from among the 600 or so which have been identified.

The Val Camonica is a long valley running up into the Alps, and it is probable that it has always been a highway for people passing north and south. But why for 30 miles or so folk should have taken the trouble to cover rocks with stylized figures of animals, men and signs remains a mystery. It is easy to talk about ritual, but that does not answer the question. Why the ritual, and what was it ? Similar rock art complexes are known, the most famous being those surrounding Monte Bego in the Ligurian Alps. While there is a certain similarity with those of the Val Camonica, there are also notable differences (the characteristic halberds of Monte Bego seem to be replaced by spears at Val Camonica and I do not remember any stags at Monte Bego), and in any event their connexion would rather be with the earlier series at the Val Camonica than with the later. At Monte Bego there is a thunderstorm almost daily at 3 p.m., due to the fact that it is the first high mountain inland from the hot Riviera coast. Local peasants, when asked what the weather will be, still say, "Let me see what the devil at Monte Bego is doing". One can imagine a reason for a ritual to take place from time to time at that mountain, but at Val Camonica such a reason would seem to be absent.

M. Anati is to be congratulated on producing a very useful and much-wanted work. Two criticisms must be added. No general index is supplied, and while there are references to a few works in the text, there is no bibliography. This is a real nuisance. French publications seldom carry any index : a policy to be questioned. In the present case, its absence is a great inconvenience. But these two defects must not be allowed to detract from the real value of M. Anati's excellent work. MILES BURKITT

HYPOTHERMIA AND THE EFFECTS OF COLD

THE modern investigation of hypothermia in man can be said to date from the work of Temple Fay and G. W. Smith, carried out during 1938–39. They cooled patients suffering from inoperable carcinoma, in the hope that the lowered temperature would affect the new growth more than the rest of the body. The clinical work was complemented by physiological work by D. B. Dill and W. H. Forbes on hypothermic patients.

During the Second World War hypothermia became important as a factor in survival at sea. Shipwreck survivors rescued after prolonged immersion frequently died because of lowered body temperature. Much work on the effects of body-cooling was thus stimulated, with emphasis on the treatment of hypothermia rather than on its clinical use. After the War, A. H. Hegnauer and his associates at Boston started a systematic investigation of the physiology of hypothermia in the dog, and about the same time W. G. Bigelow began his work at Toronto with the possibility of using hypothermia as a surgical tool.

Since 1950, the subject has advanced very rapidly, particularly as the surgical advantages of hypothermia have become apparent. Smith and Fay reduced body-temperature to between 30° C. and 32° C., and this was a hazardous procedure. For a long time it was found to be dangerous to lower the temperature to below 27° C. Now C. E. Drew and his colleagues cool their patients to below 15° C.

A recent issue of the *British Medical Bulletin* contains a fascinating collection of articles describing present investigations and how the techniques of hypothermia are being used in medicine and surgery (17, No. 1 ; January 1961 : Hypothermia and the Effects of Cold. Pp. 1–78+xvii. London : British Council, 1961. 20*s*.). The articles include one by R. W. Salt on the resistance of poikilothermic animals to cold ; hibernation in mammals by Dr. L. Harrison Matthews ; local cooling in man by Dr. R. H. Fox ; physiological effects of continued cold on animals and man by J. S. Hart ; biochemical changes in exposure and acclimatization to cold environments by Dr. F. Depocas; the technique of induced hypothermia by Drs. I. K. R. McMillan and E. S. Machell; profound hypothermia in cardiac surgery by Dr. C. E. Drew. Other articles include accounts of experimental deep hypothermia and the circulation in hypothermia; metabolism in hypothermia; hormones in hypothermia; the central nervous system in hypothermia and the effect of temperature on the response to drugs; and sensitivity of hypothermic mammals to X-irradiation. Prof. A. S. Parkes has acted as co-ordinator of the whole series.

OPEN FORESTS IN TROPICAL AFRICA

PUBLICATION No. 52, issued by the Scientific Council for Africa South of the Sahara, contains selected papers presented at a conference of British, French, Belgian and Portuguese specialists held at Ndola, Northern Rhodesia, during November 17–23, 1959, and also the recommendations made and the conclusions reached*.

The conference considered the forestry problem of what is generally referred to as miombo woodland which, from Katanga (Congo) to Southern Rhodesia, covers some 670,000 square miles. The term miombo embraces several forest types ranging from dry high forest to savannah-woodland, but *Brachystegia* species are fairly typical of the tree canopy.

The sylviculture and management of the miombo woodland are made difficult by the large areas, the damage caused by fires, the low proportion of valuable species, the slow rate of growth, the long haulage distances, the limited uses of timbers which are not easy to work, slow to season, not durable and sometimes not possible to impregnate. *Pterocarpus angolensis* and the so-called Rhodesian teak, *Baikiaea plurijuga*, provide timber for constructional work and for joinery, but most of the other timbers are used for fuel-wood, mine-wood and smelter poles in the Copper-belt.

---

* Scientific Council for Africa South of the Sahara. CSA/CCTA Publication No. 52. Pp. 126. (London: Bureau of Publications, CCTA/CSA Secretariat, Watergate House, York Buildings, W.C.2, 1960.)

As a result of burning experiments, covering a period of 26 years in Northern Rhodesia, there is ample evidence to confirm that late burning is most damaging to the vegetation and soil, complete protection is an unattainable ideal and that early burning is practical and beneficial by preventing damaging late fires, allowing the stocking of the trees to increase and not causing erosion.

Attempts are being made to resolve some of the problems of miombo woodland. There is a need for coniferous timber and it is being imported from Canada at great expense into the Copper-belt. In tropical and sub-tropical Africa mountain grassland is used largely for the planting of exotic conifers, but Northern Rhodesia has none. However, as a result of a well-planned, cautious programme, instituted some 20 years ago, tropical pines are being planted in suitable soils in miombo woodland.

A similar programme has been instituted in Katanga, but with eucalypts, and it is estimated that about one-hundredth of the area is required to yield the same amount of produce for the mines as can be obtained from miombo woodland.

It is good to note that not only were the problems affecting such large areas expressed at the Ndola Conference but also that steps have been put in train to exchange information between member Governments and to collect further information required for a fuller understanding of miombo woodland so that it may be put to better use.

AN A.C. MODULATED FLAME IONIZATION TRIODE

By J. MIDDLEHURST and B. KENNETT

Divisions of Physics and Food Preservation, Commonwealth Scientific and Industrial Research Organization, Sydney

A CONVENTIONAL flame ionization detector operates as a diode, the ionization current of which is measured with a d.c. amplifier. The effects of drift and fluctuations in gain associated with such d.c. systems may be avoided by the use of an a.c. system. This may take several forms: the diode may be supplied with an a.c. voltage[1]; the d.c. current out of the diode may be converted to a.c.; the flow of gas to the jet may be modulated with an oscillating diaphragm; or the diode may be converted to a triode and used as an a.c. amplifier.

In a recent account[2] of the discussion at the third International Symposium on Gas Chromatography, L. Ongkiehong is reported to have suggested the insertion of a third electrode into the flame ionization detector. We have been investigating the properties of such a triode system for some time, and preliminary results are presented here. The triode detector has a large output and needs no further amplification of the signal, allowing a considerable reduction in associated equipment. By a suitable choice of operating conditions, the detector can have a linear or approximately logarithmic response.

The system used consists of a hypodermic needle (0·4 mm. int. diam.) as a jet and a 1-sq. cm. 48-mesh platinum gauze anode situated about 9 mm. above it. The third electrode, termed by us the grid, is a cylinder 4 mm. int. diam., 2·5 mm. long, wound from 0·5-mm. platinum wire, placed coaxially and approximately level with the jet.

Such a system may be treated in the same way as a triode valve. Fig. 1 shows typical characteristic curves taken at a constant flow of 10^{-8} gm./sec. of ethylene. Only characteristics involving positive anode potentials and currents are given, superimposed on which are two load lines *BC* and *DE*, each of slope 2×10^9 ohms.

The way in which the system is used is as follows:

(1) Suitable values are chosen for the d.c. anode supply voltage and load resistor.

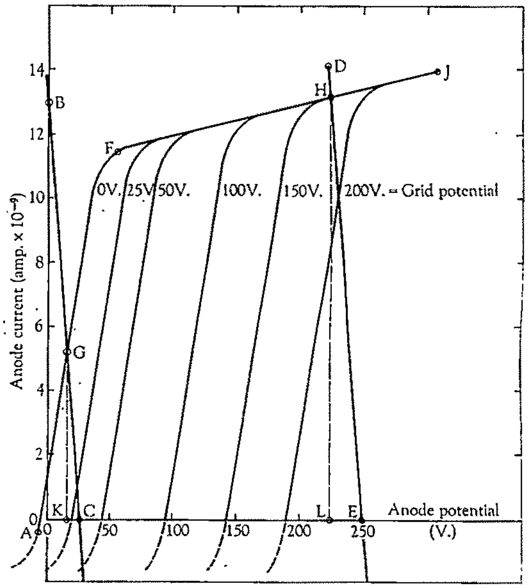

Fig. 1. Characteristic curves of flame ionization triode. Nitrogen flow, 50 ml./min.; hydrogen flow, 50 ml./min.; air flow, 800 ml./min.; ethylene flow, 10^{-8} gm./sec.; anode height, 9 mm.; grid height, 0 mm.

(2) A sinoidal voltage having a peak-to-peak value equal to the anode supply voltage is applied to the grid.

(3) A d.c. voltage equal to half the anode supply voltage is also applied to the grid, so that the voltage on the grid will vary sinoidally between zero and the anode supply voltage.

(4) The peak-to-peak a.c. voltage developed at the anode is transferred by a cathode follower to a phase-sensitive detector, the d.c. output voltage of which is related to the ionization current in the flame.

In Fig. 1, if C volts d.c. is supplied to the anode through a resistor of 2 × 10^9 ohms (corresponding to load-line BC), the peak-to-peak a.c. voltage developed at the anode is KC; similarly, if anode supply voltage E and load-line DE are chosen, the output voltage is LE.

If the ethylene flow-rate is doubled, the other flow-rates remaining unchanged, the height of the portion FJ of the curve doubles and the slope of AG doubles; consequently voltage LE is doubled but voltage KC only increases slightly. If anode supply voltage C and load-line BC are chosen, the detector will be approximately logarithmic for ethylene flow-rates greater than about 5 × 10^{-9} gm./sec. If anode supply voltage E and load-line DE are chosen, the detector will be linear up to, say, 10^{-7} gm./sec., and logarithmic for greater flow-rates. Thus, by suitable selection of anode supply voltage and load resistor the detector may be made approximately: (*a*) linear, (*b*) logarithmic, or (*c*) linear up to any desired flow-rate and logarithmic thereafter.

The flame ionization triode, like its vacuum counterpart, has both grid-anode capacitance and transit time effects. Because of the latter, considerable phase-shift occurs at frequencies above 20 c./s.; consequently it is preferable to apply sine waves rather than square waves to the grid. With the particular configuration used, the optimum frequency is 13 c./s. The grid-anode capacitance is of the order of 0·05 *p*F. which, at this frequency, gives a signal of about 1 volt peak-to-peak a.c. with no flame. This constant signal is removed by introducing an equal signal of opposite phase into the anode voltage supply. Constant background signals, caused by the hydrogen flame, are removed in the same way. This capacitance could be reduced by introducing further electrodes to form a tetrode or pentode; alternatively the grid may be earthed and the a.c. voltage applied to the jet.

One particular advantage of this type of detector is its high output. Applying 100 V. peak-to-peak to the grid and using a cathode follower with a measured input impedance of 2 × 10^9 ohms, followed by a phase-sensitive detector but without any intermediate amplifier, some 20 volts d.c. is available at the output of the phase-sensitive detector for an ethylene flow-rate of 10^{-8} gm./sec. The noise-level of the system in these circumstances is about 100 μV., which suggests an attainable detection limit of the order of 10^{-13} gm./sec.

PHOTOLYSIS OF NITROMETHANE

By Dr. A. J. C. NICHOLSON

Chemical Research Laboratories, Commonwealth Scientific and Industrial Research Organization, Melbourne

IT is reasonably certain[1] that the main primary step in the pyrolysis of nitromethane (at pressures below 200 mm.) is a breaking of the C—N bond and that a fraction of the methyl radicals produced form methane by hydrogen abstraction. Gray, Yoffe, and Roselaar[1] suggested that the mechanism of the photolysis is essentially similar, namely, a primary split:

$$CH_3NO_2 + h\nu \rightarrow CH_3\cdot + NO_2. \qquad (1)$$

On the other hand, Brown and Pimentel[2] found that when nitromethane in solid argon at 20° K. was illuminated it isomerized to methyl nitrite, and considered that all the products resulted from the secondary photolysis of the nitrite. They stated "there seems to be no evidence preventing the assumption that the primary act of photolysis of gaseous nitromethane is the same as in the (argon) matrix", and as they found no evidence for the products nitrogen peroxide, methane or ethane they considered that (1) did not occur. The authors of both these papers claim that their primary step explains the photolysis products found for gaseous nitromethane by Hirschlaff and Norrish[3]. It is not obvious how either postulate explains the appearance of nitrogen as a major product. It seemed useful, therefore, to re-examine the gas phase photolysis and, in particular, to analyse the products for methane.

22 mm. of degassed nitromethane were photolysed at 27° C. in a quartz cell. (I am indebted to Mr. I. Brown of these Laboratories for a sample of pure nitromethane. Its mass spectrum was essentially identical with that quoted in "Mass Spectral Data of the American Petroleum Institute Research Project 44", Carnegie Institute of Technology, Pittsburgh, Pa.) The light source was a 250-W. medium pressure mercury arc used both directly and through a Jena *BG*3 filter which cut out all light below 2500 Å. The products uncondensed by liquid air were expanded into 1-l. flask and analysed with a mass spectrometer. The results were recorded in Table 1 in units of 10^{12} molecules/ml. of illuminated volume/sec.

Table 1

Product Light	CO	N_2	NO	H_2	CH_4	C_2H_6
None		0·9	1·7			
,,		0·1	0·5			
Full arc	159	23	76	45	15·0	0·6
,, ,,	144	18	85	46	14·5	1·1
,, ,,	161	21	79	45	14·2	0·5
Filter	32	4·6	14	9·3	0·81	0·04
,,	13	4·2	20	5·3	0·86	0·07
,,	23	3·3	19	6·8	0·90	0·09

Although the amount of methane was small the analysis was quite unequivocal since it depended on peaks at masses 15 and 16 to which there was practically no contribution from other gases present. The analysis for nitrogen was less accurate since it depended on the residual at mass 14 after subtraction of the contribution from nitric oxide and methane. Nevertheless its identification was quite certain. Small peaks, about twice the height of the mass spectrometer background, at masses 26 and 27 were in the right ratio to be produced by ethane and were tentatively so assigned.

A second fraction, of products uncondensed at −79° C., was examined, but the mixture was too complex for quantitative analysis. Nitrogen peroxide, carbon dioxide, nitric oxide and methyl alcohol were identified positively. A peak at mass 29 together with other residuals seemed fairly certainly due to formaldehyde. After subtraction of the contribution from carbon dioxide, residuals at masses 44 and 45 were in the ratio of 25 : 1 which agreed exactly with the ratio of these peaks in a sample of formaldoxime. It appeared unlikely that any of the mass 44 peak was due to nitrous oxide.

A solid white polymer was also formed during the photolysis ; wildly erratic results for the carbon monoxide and hydrogen analyses were obtained until the polymer was removed after each run. The product obtained by heating this polymer gave major peaks at masses 45, 30, 29 and 15 consistent with the view that it was a mixture of formaldehyde and nitrosomethane.

Except for the nitrogen, all the products found are those to be expected from the primary split (1). Methane is formed by:

$$CH_3\cdot + CH_3NO_2 \rightarrow CH_4 + \cdot CH_2NO_2 \qquad (2)$$

and the $\cdot CH_2NO_2$ radical probably splits to give formaldehyde and nitric oxide:

$$\cdot CH_2NO_2\ (? + M) \rightarrow CH_2O + NO. \qquad (3)$$

Oxygen is present from the secondary photolysis of nitrogen peroxide, and it is well known[4] that oxidation of methyl radicals leads to carbon monoxide, carbon dioxide, methyl alcohol and formaldehyde. The reactions:

$$CH_3\cdot + NO_2 \rightarrow CH_3O\cdot + NO \qquad (4)$$

$$CH_3\cdot + CH_3NO_2 \rightarrow CH_3O\cdot + CH_3NO \qquad (5)$$

probably occur also. The hydrogen is produced by the secondary photolysis of formaldehyde. Finally, Coe and Doumani[5] have shown that the reaction of methyl radicals with nitric oxide leads to nitrosomethane, formaldoxime and their solid polymers. Thus the evidence obtained from these analyses gives convincing support to the view that (1) is the major primary step in the gas-phase photolysis. This postulate is consistent with the results of Brown and Pimentel[2] if it is assumed that in the gas phase methyl radicals and nitrogen peroxide disproportionate by (4) but that in the 'cage' of the solid matrix at 20° K. they combine to form methyl nitrite rather than the original nitromethane.

This work gives no support to the conclusion of Hirschlaff and Norrish that nitrogen is the major product of the photolysis. It is not clear whether their 'nitrogen' was analysed for methane and hydrogen. Nitrogen is, however, a minor product, as it is also in the photolysis of tetranitromethane[6]. Except that energy considerations would suggest a heterogeneous reaction, the mechanism for nitrogen production in these photolyses is obscure.

BIVALENT METAL IONS AS THE COUPLING FACTOR BETWEEN CELL METABOLISM AND THE RATE OF CELL MUTATION

By DR. G. G. JAYSON

Department of Chemistry and Biology, Liverpool College of Technology, Liverpool 3

ONE of the most important interactions which take place in the cell is transphosphorylation. The way phosphates enter into the energy cycles and their presence in nucleic acids has been investigated by a great number of workers. What has become clearer recently is the importance of the divalent metal ions in this process.

Thus, Ashwell and Hickman[1] showed that calcium accelerates the breakdown of adenosine triphosphate (ATP) to adenosine diphosphate (ADP) in spleen homogenates. X-rays were found to have a similar effect. As the radiations are known to deactivate enzymes, their action was ascribed to the destruction of cellular material allowing greater contact between the enzymes and ATP. More recently, Lowenstein[2,3], has demonstrated that enzymes are not necessary for the hydrolysis of ATP to ADP. Divalent ions, for example, Ca^{2+} and Mg^{2+}, alone were sufficient to bring about the transformation :

$$\text{ATP} + \text{orthophosphate (P–32)} \xrightarrow{Ca^{2+}\text{ and }Mg^{2+}} \text{ADP} + \text{pyrophosphate}$$

where: orthophosphate $= 5 \times 10^{-3}\ M$; ATP $= 1 \times 10^{-2}\ M$; $Mg^{2+} = 1 \times 10^{-2}\ M$.

The formation of pyrophosphate at these concentrations in aqueous solution by means of a non-enzymic reaction is quite remarkable. Lowenstein explained the catalytic action of the bivalent metal ions by the complex they can form with ATP ; although he is not sure whether Ca-ATP, Ca-ATP-Ca or Ca-ATP-Mg is the important entity leading to ADP formation.

The hydrolysis of condensed phosphates such as pyro- and tri-polyphosphate has been investigated in some detail[4]. It is markedly affected by changes in *p*H and the presence of metal ions (particularly calcium). Van Wazer[4], describing work by Griffith at Monsanto, has explained this on the basis of an 'activated complex' which takes the form of the metal chelate. On that basis, Ca-ATP ought to be the complex which leads to ADP.

The behaviour of the condensed phosphates and their organic derivatives (for example ATP, ADP) with respect to calcium ions in aqueous solution appears to be similar[5]. This is not surprising because the dominant ionic feature is the polyphosphate chain. To this must be added what is now known of the interactions between condensed phosphates, 'hardness' in water and metals on surfaces[6]. Fig. 1 shows the effect of mixing solutions of condensed phosphates and calcium. It is possible to get an insoluble salt $Ca_2P_2O_7$, or a soluble complex $CaP_2O_7^{2-}$.

$$(1)\ \xrightarrow[\text{in phase diagram}]{P_2O_7\text{ into calcium}}\ (a)\ P_2O_7{}^{4-} + 2\,Ca^{2+} \longrightarrow \underset{\text{insoluble salt}}{Ca_2P_2O_7}$$

$$(b)\ P_2O_7{}^{4-} + Ca_2P_2O_7 \longrightarrow \underset{\text{soluble complex}}{2CaP_2O_7{}^{2-}} \xrightarrow{\text{hydrolysis}}$$

$$(2)\ \uparrow\ \begin{matrix}\text{Calcium into }P_2O_7\\ \text{in phase diagram}\end{matrix}\ (a)\ Ca^{2+} + P_2O_7{}^{4-} \longrightarrow \underset{\text{soluble complex}}{CaP_2O_7{}^{2-}} \xrightarrow{\text{hydrolysis}}$$

$$(b)\ Ca^{2+} + CaP_2O_7{}^{2-} \longrightarrow \underset{\text{insoluble salt}}{Ca_2P_2O_7}$$

Tripolyphosphate behaves in a similar manner, but does not show as great an insoluble phase. Whether the complex is hydrolysed or not will depend on the *p*H of the solution. Once the insoluble salt has been formed, it is difficult to bring it back into solution again. In fact, it has been found that five times the stoichiometric quantity of polyphosphate is needed[7]. It follows that, whenever the calcium phosphate system passes through an insoluble phase, a time-lag must occur before the calcium can be brought back into solution and catalytic service. Also, once the insoluble calcium salt has formed, we are really working with an inhomogeneous system, as observed in detergency[6]. If calcium were to be precipitated in the cell as another insoluble salt (for example, calcium fatty acid) the same problems of solubilization would arise. The exact position taken up by the phosphates, ATP and ADP, during transphosphorylation and the build-up of nucleic acids must therefore be determined by the positions of the divalent metal ions and local conditions of *p*H.

These results, then, explain why small changes in calcium and ADP concentration have such a marked effect on the control of respiration in the cell[8]. Furthermore, the control points in phosphorylation would in fact be positions where divalent metals are to be found[9]. It can be seen from this that the part which calcium and magnesium ions play in cell metabolism is of the utmost importance.

In addition to the above it has been found that in the nucleus calcium and magnesium ion hold together sections of chromosomes[10]. That is, changes in the concentration of the ions will determine the degree of chromosomal aberration. Ethylenediamine tetraacetic acid (EDTA) was found to produce breaks in the chromosomes of *Vicia faba*[11]. *Tradescantia* grown in calcium-deficient diets showed similar results[12]. If the effect of calcium and magnesium ion concentration on chromosomal aberration were to be added to that of its action on the phosphorylating metabolism the pattern depicted in Table 1 would emerge.

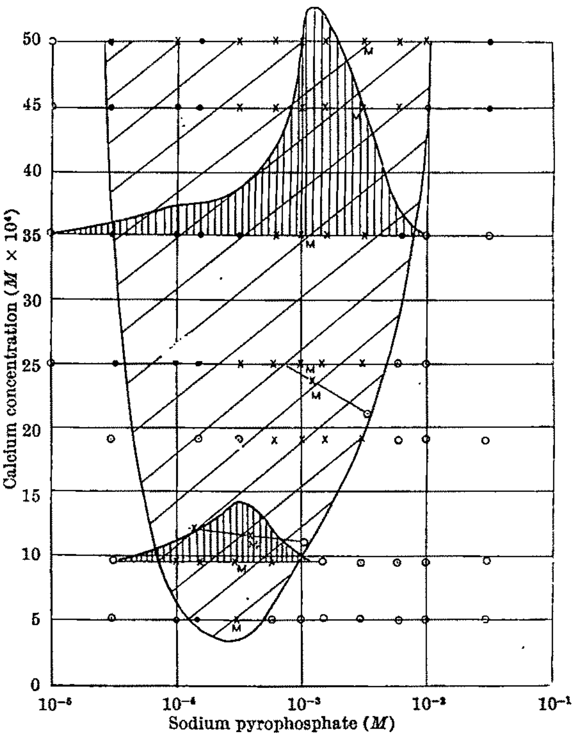

Fig. 1. Phase diagram of calcium pyrophosphate at 23°C. ×, Precipitate ; ○, clear solutions; ●, doubtful; ///, intensity of phase ; M, maximum in any series

Fluctuations in the concentrations of divalent metal ions in the various parts of the cell could arise through precipitation of an insoluble salt (for example, CaADPCa) rather than formation of the soluble complex (as in the chemistry of Ca^{2+} and $P_2O_7{}^{4-}$; see above[6]). Calcium ions removed by the former method would be virtually lost to the aqueous phase because of the time-factor involved in bringing them back into solution. This would also hold for calcium ions precipitated on walls of cell, mitochondria and nucleus. In effect, the system would have lost a homogeneous catalyst and possibly gained a heterogeneous one.

Table 1. EFFECT OF FLUCTUATION OF CALCIUM CONCENTRATION ON THE METABOLISM AND MUTATION-RATE OF THE CELL

Ca^{2+} concentration in the cell	Metabolic-rate	Rate of mutation	Mitosis rate of reproduction	State of cell
$\pm Ca^{2+}$	Normal rate of ATP breakdown	Normal number of chromosomal aberrations	Normal rate of mitosis	Normal integrated cell
$- Ca^{2+}$	Decrease in ATP breakdown	Increase in chromosome* aberrations (including mutant which allows cell to operate at lower Ca^{2+} concentration)	Mitosis retarded	Differentiation of the integrated cell (benign)
$+ Ca^{2+}$	Increase in ATP* breakdown (further increase for mutant which allows all to operate at lower Ca^{2+} concentration)	Decrease in chromosome aberrations (that is, holding on to any mutant produced in $- Ca^{2+}$ phase)	Mitosis increased (particularly for mutant) * Frequency of sensitive stage in cell division increased, that is, particularly sensitive to X-rays	Rapid (malignant) growth of non-integrated cell

—— show the effect of cycle in Ca^{2+} concentration.

* shows points where X-rays have an effect. They will also increase the permeability of the membranes.

If the cell, in order to carry on with its metabolism (transphosphorylation) removes calcium or magnesium out of the nucleus into the cytoplasm, it will increase the number of chromosomal aberrations. One of these may be a mutation which allows the cell to live with a metabolism at the new, lower calcium-ion concentration. When the original calcium-ion concentration is restored (by complexed calcium entering from outside the cell, or the calcium precipitate eventually redissolving into the aqueous phase) the cells with the 'low calcium metabolic' mutant would show a much higher metabolism and rate of mitosis. As increased calcium-ion concentration reduces chromosomal aberration, there would be no possibility of reversing the mutation or adapting it as before. This sequence of events is shown in Table 1.

Neoplastic growth induced by other agents would exert its effect at some point in the calcium control. For example, some carcinogens may induce this calcium cycle by interfering with the respiratory (electron and proton transfer) system, for example, phenanthrene. On the other hand, such compounds may cause precipitation of the calcium ions on the cell walls. X-rays will produce interactions at a number of points in the cell and these are shown (by an asterisk) in Table 1.

It should be possible to encourage the formation of 'rapidly metabolizing' mutants by submitting the cells to a diet which is alternatively low and high in calcium content. Conversely, mutation of normal cells should be suppressed by the introduction of a calcium 'buffer'[13] (for example, complex of calcium) into the cell. The way to decelerate the high rate of mitosis of mutant cells would be withdrawal of Ca^{2+} (for example, by means of EDTA). 'Synkavit' (tetrasodium 2-methyl-1, 4-methyl-1, 4-naphthohydroquinone diphosphate) which has been used by Mitchell[14] for the treatment of skin cancer and rectal adenocarcinoma probably acts in the same way. However, application of Ca^{2+} or Mg^{2+} depressants would induce chromosomal aberrations in normal neighbouring cells and, therefore, would have to be carried out locally. (From a medical point of view, the agent for removing calcium would have to be injected into the tumour or, if possible, the tumour would have to be bathed with such a solution.) There are obviously a great number of biological and medical experiments which could be based on the theory expressed above.

REVERSAL OF DIURNAL TEMPERATURE RHYTHMS IN MAN

By G. W. G. SHARP*

Institute of Clinical Research, Middlesex Hospital Medical School, London, W.1

RECENTLY, while working with the University of Nottingham Department of Pharmacy Expedition to Spitsbergen, the opportunity arose to study the diurnal temperature variations in a group of 6 men and 2 women, who were subjected to sudden reversal of their activity-sleep and light-darkness schedule. The subjects lived a controlled life of activity, diet, time of meals and they went to bed and awoke at set times each day. Spitsbergen provides an ideal environment for this type of work during the summer months because of the 24-hr. daylight and even temperatures. It was necessary for the subjects to sleep with blindfolds on to ensure the alternation of light and dark. They retired at 22.30 hr. each night and arose at 07.00 hr. under control conditions. On any test day, body temperatures were recorded every 3 hr. from rising until 22.00 hr. and again on rising the following morning.

Temperatures were taken using clinical thermometers placed in the armpit. It would have been desirable, but was impossible in the circumstances, to record rectal temperatures. Oral temperatures were found to be unreliable in an environment where facial cooling was appreciable so that skin temperature was the only possibility, and the armpit a very convenient site. After 4 test days on the control routine (periods 1–4) the subjects reversed their routine exactly on a 12 hr. basis. Thus they arose at 19.00 hr., worked through the night and retired at 10.30 hr. By sleeping with blindfolds on, the day became an artificial 'night' and the night became 'day'. Due to the 24 hr. daylight, there was little difference between night and day. In order to minimize the stress during reversal the subjects slept all night on the last control period, had breakfast, and then retired to sleep again, from 10.30 to 19.00 hr. From this point they arose, had breakfast again and worked through the night. Temperature records were made as before on test days, 2, 4, 6 and 8 days after reversal (periods 5–8). After 14 days on this routine, a reversal back to normal was made and the adaptation of temperature rhythms noted. Tests were performed again on four alternate days after the change (periods 9–12).

Daily routine

Periods 1–4 and 9–12 (hr.)	Periods 5–8 (hr.)	
06.50	18.50	Reveille, blindfolds lifted.
07.00	19.00	Body temperature taken, weather records made.
07.30	19.30	Breakfast.
10.00	22.00	Body temperature taken.
13.00	01.00	Body temperature taken. Lunch.
16.00	04.00	Body temperature taken. Tea.
19.00	07.00	Body temperature taken, weather records made. Dinner.
22.00	10.00	Body temperature taken.
22.30	10.30	Subjects to bed, blindfolds on.
07.00	19.00	Body temperature taken.

---

* Formerly lecturer in pharmacology, Department of Pharmacy, The University of Nottingham.

Table 1. Diurnal Body Temperature Rhythms expressed in Degrees Fahrenheit and Standard Deviation

Time Period	07.00	10.00	13.00	16.00	19.00	22.00	07.00
1–4	96·6 ± 0·9	97·3 ± 0·9	97·0 ± 0·9	97·3 ± 0·7	97·2 ± 0·8	97·4 ± 0·8	96·7 ± 1·0

9	97·2 ± 0·6	97·5 ± 0·8	96·9 ± 1·1	97·2 ± 1·1	97·0 ± 1·0	97·1 ± 1·0	96·8 ± 0·9
10	97·1 ± 0·7	97·9 ± 1·1	97·7 ± 0·9	97·7 ± 0·5	97·1 ± 0·9	97·6 ± 1·0	96·7 ± 1·0
11	96·9 ± 0·7	97·5 ± 1·1	97·5 ± 0·9	97·6 ± 0·9	97·5 ± 0·7	97·4 ± 0·7	97·0 ± 0·5
12	97·0 ± 0·9	97·9 ± 0·9	98·0 ± 0·8	97·8 ± 0·9	97·6 ± 0·7	97·6 ± 0·7	97·3 ± 0·5

The results are shown in Table 1, where the average temperature during each period is recorded.

The diurnal variation exhibited by subjects, under these particular experimental conditions, was characterized by a rapid rise of temperature from waking to 10.00 hr. followed by a decrease, though temperatures remained high for the rest of the day. A slight rise of temperature occurred after each meal though one may not assume any significance in this correlation. During the night, temperatures fell to low values. In period 5, two days after the reversal of routine, the waking temperature was high and no rise occurred in the following three hours. A slight rise to lunch-time was followed by afternoon and evening temperatures which were below the waking value. It was clear that the temperature rhythm had not become adapted, by reversal, to the new time-scale, and that the temperatures recorded from lunch-time on were 'night values'. During the second 'night', however, the temperature rose slightly and to the normal waking value.

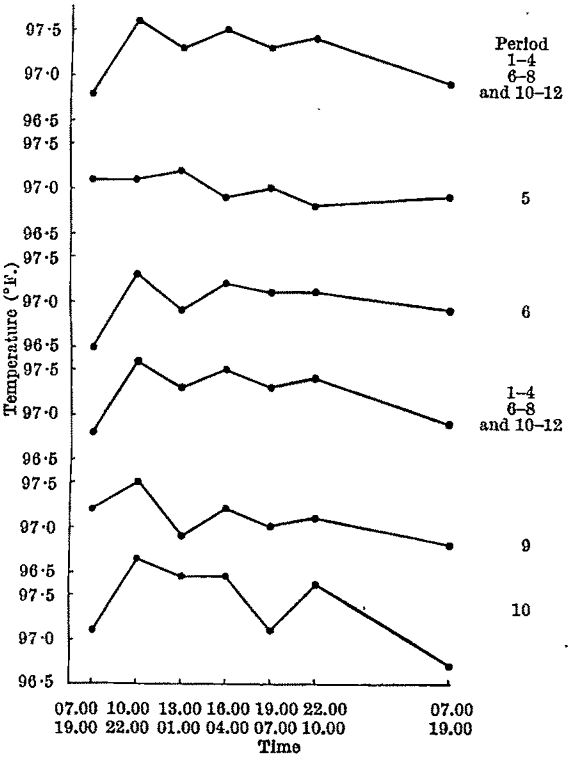

Fig. 1. Diurnal temperature variation

In period 6 a fairly typical diurnal variation was observed with a sharp rise after waking, a slight fall following, raised 'daytime' values and a fall at 'night'. Thus reversal of the diurnal temperature rhythm had occurred within 3–4 days of reversal of routine. After adaptation and two further test days a return to normal was accomplished by a further 12-hr. time shift. Period 9 represents the test day 2 days after the reversion to normal. The waking temperature was elevated, as in period 5, and only a slight rise occurred during the next 3 hr. The pattern from there onwards was similar to the control pattern except for lower temperatures and only a slight night fall. In period 10 a steep waking rise and night fall were both present. Reversion of rhythm to normal had again occupied 3–4 days. The pattern of diurnal temperature variations are shown in Fig. 1.

A diurnal variation of body-temperature was noted shortly after the introduction of thermometers into clinical practice. Warter[1], for example, recorded minimum temperatures in the early morning and maxima in the evening. Ogle[2] in the same year recorded afternoon maxima and also stated that the variations were greater in men than in women. A review of the earlier literature has been given by Woodhead and Varrier-Jones[3]. They pointed out the pitfalls of this type of work and emphasized the importance of sleep and light, the conditions and means of temperature measurement, and the fact that even when subjects are in bed for 24 hr. or more the diurnal temperature rhythm still persists.

Several investigations into the diurnal rhythm, and particularly its persistence, have been made. Kleitman and Doktorsky[4] have shown that the sleep-wakefulness cycle is an individually acquired phenomenon depending on the cerebral cortex for establishment and maintenance, and that the body temperature rhythm parallels the development of the sleep-wakefulness cycle. Observations on infants confirm the relationship between activity and temperature rhythms, though Metz and Andlauer[5] were unable to correlate temperature curves with variations of energy metabolism. That the temperature rhythms are developed by a process of acculturation is undoubted. Experiments on rabbits have shown that feeding habits play an important controlling part[6]. In man, fasting has been shown not to eliminate the rhythm. Kleitman found that diurnal temperature curves may differ in individual subjects with extremes of morning or early evening peaks[7], and also that after waking the morning rise in temperature may be followed by a 'plateau' effect for the remainder of the day and early evening[8]. In monkeys, the temperature rhythm has been reversed by reversal of lighting, while gradual extinction occurred after one week in darkness[9]. The diurnal rhythm has been reversed in man by reversal of daily routine[7], though resistance to change has been noted. Individuals may vary greatly in their adaptability, some failing to adapt after three weeks on night work, and others become adapted in a few days. Burton[10] found that his own temperature rhythm required 3–4 days to become accommodated with English time after a flight from Canada. This involves a time-shift of 5 hours in the daily routine.

In Fig. 1 selected periods are used to illustrate the diurnal variation, the intensity of the morning rise and the adaptation to a reversed routine. Reversal of the diurnal temperature curve occurred in 3–4 days and all the subjects showed the same general pattern. The normal temperature observed on waking on the third morning after reversal of routine is indicative that the rhythms were becoming stabilized on the new routine while the typical post-waking rise was present four days after reversal. Throughout the test periods no variations occurred in environmental temperatures sufficient to invalidate any comparison between periods. The temperature variations are clearly not directly dependent on physical activity or food intake because reversal did not occur immediately when the activity-sleep routine was reversed. They depend ultimately on habit and environment, with light as the most likely controlling stimulus. The time of adaptation reported here agrees well with Burton's observation of 3–4 days to become adjusted to a 5-hr. time-shift.

One further point of interest is that etiocholanolone causes a rise of body temperature after injection which may last for several hours[11]. In view of the diurnal variation of ketosteroid output which is greater by day than by night it was thought that this might be influencing the temperature rhythm. In 4 of the male subjects of this work, a simultaneous study of keto- and ketogenic-steroid excretory patterns was made. Reversal of the keto- and ketogenic-steroid pattern occurred in 2 and 6–8 days respectively. Because the temperature rhythm was reversed in 3–4 days it seems unlikely that these steroids play an important part in the control of body-temperature rhythms though this does not exclude the possibility that they exert some effect upon temperature-levels.

I am grateful for financial support from: a Scientific Investigations grant-in-aid administered by the Royal Society, the Pharmaceutical Society of Great Britain, the Nottingham University Union of Students and May and Baker, Ltd. In addition, I wish to express my thanks to the members of the expedition, to all the firms and individuals who helped this project, to E. C. Smith and Sons, Ltd., for the gift of clinical thermometers, to the Nottingham University Exploration Society for the loan of equipment, and to Dr. H. J. Vipond and Mr. S. A. Slorach for performing the steroid analyses.

TWO LINKED GENES SHOWING A SIMILAR TIMING OF EXPRESSION IN MICE

By KENNETH PAIGEN and WERNER K. NOELL
Roswell Park Memorial Institute, Buffalo, N.Y.

TWO single gene mutations in the mouse show similar timing of expression during post-natal development. The two mutant alleles were found to produce nearly normal phenotypes until some critical time after birth following which normal differentiation is arrested. The first of these genes, originally reported by Morrow, Greenspan and Carrol[1] in *C3H* mice is expressed in the recessive state by a deficient production of the enzyme β-glucuronidase[2,3]. It has recently been demonstrated that homozygous mutant animals (*gg*) produce the enzyme in some tissues, notably liver, only until a certain post-natal stage, after which a progressive decline sets in and the enzyme ceases to accumulate further. Wild-type (*GG*) stocks produce the enzyme throughout growth[4]. A representative experiment is shown in Fig. 1.

The second mutation is that responsible for a recessive hereditary visual cell degeneration recently described from several laboratories[5–8]. At birth, the retinæ of mice homozygous for the recessive allele (*rd*) do not differ significantly from those of control animals, and post-natal differentiation at first proceeds normally. Beginning, however, at the onset of the most rapid phase of visual cell differentiation on the tenth day, and just after the visual cells have become minimally responsive to light stimulation, the cells die. By the fourteenth day, 50 per cent of the visual cells have disintegrated; at three weeks of age practically none remain, and the animals are blind. This process has been described in detail[8].

Both mutations are characteristic of *C3H/Ha* mice, and the experiments to be described show that in addition to sharing a similar pattern of expression, they are closely linked on the same chromosome. They do not, however, appear to control the same physiological process.

In these experiments β-glucuronidase was assayed by a modification of the phenolphthalein glucuronide procedure of Talalay *et al.*[9]. Activity is expressed as μgm. of phenolphthalein formed per hour when assayed at 56° C. Presence or absence of visual cell degeneration was ascertained by the electrical response to light stimulation (electroretinogram) and histological examination[8].

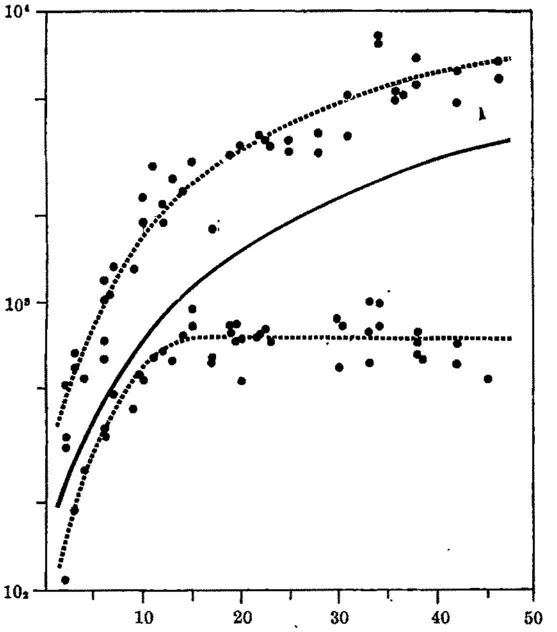

Fig. 1. The total enzyme content of liver plotted as a function of days of age in a population of mice segregating for the *g*-*G* alleles (that is, the progeny of a *gg* × *Gg* cross). Each point represents a single mouse and enzyme activity is expressed as total units per liver. The solid line is the growth curve of liver in this population expressed as mgm. × 10 dry weight. The dashed lines are drawn to indicate the growth curves of the enzyme in the two classes of progeny

It is apparent from Table 1, which lists the results obtained with a number of mouse strains, that *C3H/Ha* mice show both mutations. In *AKR*, *C3H/St* and *CFW* lines the *g*-*G* and *rd*-*Rd* allelic pairs are expressed independently of each other. The *C3H/St* and *CFW* are blind, but have high liver glucuronidase, whereas the *AKR* animals show no visual cell degeneration, but have low glucuronidase-levels. Evidence that the two loci do not affect a common function was also obtained from examination of *Ha/ICR* Swiss mice. The *Ha/ICR* Swiss are a deliberately non-inbred population. Among mice of this stock approximately 13 per cent (59/444) were blind and all (47/47) had high enzyme. That the genetic factor responsible for the visual defect in Swiss mice involves the same locus as that in the *C3H* is indicated by the failure (0/102) to observe sighted offspring of *C3H/Ha* × Swiss matings. Also, the behaviour of the *rd* allele in various other crosses was independent of its origin.

Table 2. LINKAGE OF GLUCURONIDASE AND HEREDITARY VISUAL CELL DEGENERATION

gG rd Rd × *gg rd rd*

	Blind	Sighted
High enzyme	1	33
Low enzyme	23	2

The crosses used were (*C3H/Ha* × *DBA/2*) × *C3H/Ha* and (*DBA/2* × *C3H/Ha*) × *C3H/Ha*. In crosses of the first type, the *C3H* carried the milk factor; in those of the second type, they did not.

The F_1 animals of the cross *C3H/Ha* × *DBA/2* are heterozygous at both loci and were indistinguishable from the dominant *DBA/2* parent. Examination of the offspring of a backcross of the F_1 to the *C3H* parent showed that the two loci are linked, being approximately 5 cross-over units apart (Table 2). Other linkages of the *Rd* or *G* genes are not known. In the present experiments neither factor was linked to sex, or to the coat colour genes *A*, *B* and *D*. In addition, these loci were not linked to the H-2 genic complex[10]. It has been reported that *Rd* is not linked to pigmy[11] or silver[12], and *G* is not linked to the colour genes, *A*, *B* and *C*[3]. These facts eliminate their location on linkage groups I, II, IV, V, VIII, IX or XX[13].

For the *rd* allele, although differentiation of the visual cells is blocked and cell death ensues, no effect is observed in the other retinal cells of the same ontogenetic origin, the pigment epithelium, the bipolar cells, and the ganglion cells. Similarly, for the *g* allele, although enzyme ceases to appear in the liver after the seventeenth day, enzyme production in the spleen is maintained throughout its growth. For both of these loci expression of the recessive alleles involves a nearly normal function until in some tissues, at a time characteristic for each, functional failure occurs. Despite these similarities, the two genes are separable by crossing-over and do not appear to involve a common function.

Although the genetic linkage observed may be purely fortuitous, in view of the similarities of the two loci the possibility must be considered that their linkage reflects the functional organization of the chromosomes.

A number of reports, stemming from the original observation of Beerman[14], have demonstrated that characteristic chromosomal regions swell and then shrink in the cells of particular tissues at certain stages in development, and the experiments of Briggs and King[15] suggest that differentiation may involve a concomitant loss of genetic totipotency among tissue nuclei. In the light of these findings several investigators have again proposed that the primary control mechanism in differentiation is a nuclear process involving differential gene activation or genetic segregation among the developing cells. Strong genetic support for a nuclear control comes from the experiments of McClintock[16–18], showing that a class of genetic elements exists that control the time during development at which secondary genetic events may occur.

The report of Callan and Lloyd[19] on the heterozygosity of puffing suggests that different alleles of the same gene can react differently to such control mechanisms during development, as appears to be

PHYSICS DEPARTMENT LIBRARY.

the case with glucuronidase and hereditary visual cell degeneration. They found that in the oocytes of *Triturus* neither, one, or both members of a chromosome pair may show puffs at a given locus. The finding that although cells from different individuals differed widely, all oocytes from the same animal showed identical configurations at all sites, indicated that pairs of alleles were involved in which one member forms puffs and the other does not.

If the findings reported here are considered in relation to these cytogenetic phenomena, they suggest that particular chromosomal regions may be specialized to control the timing of expression of the loci within them, and thus provide a nuclear regulation of differentiation. More serious consideration of this hypothesis must await the finding of other cases of close genetic linkage between genes showing similar patterns of physiological expression.

We are indebted to Drs. T. S. Hauschka and D. B. Amos for the *C3H/Ha* and *DBA/2* mice used in these experiments, and to Dr. L. S. Strong for the other mouse strains studied.

AMINOGLYCOLIPIDS AND GLYCOPROTEINS OF HUMAN BRAIN

I. Quantitative Fractionation of Brain Glycolipids by Silicic Acid Chromatography

WHILE there are a number of methods by which the glycolipids of mammalian brain may be individually isolated and purified, a method would be desirable whereby all the glycolipids of brain could be quantitatively separated and recovered, and their concentrations and other properties compared between individual brains. This is of interest not only with reference to the pathological lipodystrophies[1], but also with reference to the possibilities for chemical individuality of these substances in normal brain[2].

Since silicic acid chromatography has been found to be useful in the separation of both synthetic and native lipid mixtures[3], it was applied to the present problem. Whereas gradient elution of selected lipids from silicic acid columns had been found effective in the quantitative separation of a selected group of brain lipids[4], there was no evidence to indicate that a total hot alcoholic extract of brain lipids might be resolved quantitatively by these methods. With the desire to obtain quantitatively reproducible fractions which might then be compared in brain specimens from different individuals, a stepwise elution procedure was adopted, with quantitative exhaustion at each step of all the solids which could be removed from the column with a given solvent mixture.

Fresh whole bovine cerebral hemispheres, freed of investing meninges and blood vessels, were extracted with hot methanol as previously described for the isolation of brain ganglioside[5]. This procedure has been used by numerous investigators[6] for the preliminary extraction of cerebrosides and related glycolipids. In the course of preparation of brain ganglioside the filtered hot methanolic extract is allowed to stand at 4° C. for 48 hr., during which time a precipitate forms. The precipitate is filtered in the cold, then taken up at room temperature with chloroform – methanol (2 : 1), and partitioned twice with water. The upper phase contains the bulk of the brain ganglioside and other hexosamine-rich material present in the precipitate (and discussed in the next communication), and the resultant lower phase contains the other glycolipids and phospholipids. This lower phase material is taken to dryness by vacuum distillation at 60° C., taken up with minimal amounts of chloroform – methanol (2 : 1), allowed to dry at room temperature, and stored in a vacuum desiccator.

Silicic acid (Baker's reagent grade) was dried overnight at 105° C. To columns 40 mm. × 600 mm. with a fritted disk of coarse porosity was added a thoroughly mixed suspension of 250 gm. of silicic acid and 500 c.c. of chloroform – methanol (2 : 1) and additional chloroform – methanol added until a total of 1,250 c.c. were used. When the chloroform – methanol had run through to the level of the silicic acid, 1,000 c.c. of chloroform was added until the column was translucent and free of opacities[4]. The column was charged with 1,000 or 2,000 mgm. of lower-phase material in chloroform. The solvents utilized for elution were first chloroform, then mixtures of chloroform – methanol with increasing amounts of methanol, and finally pure methanol. The entire fractionation was done in a constant-temperature room at 25 ± 2° C. Fourteen fractions were thereby obtained (Fig. 1). In addition to the good general separation previously observed with more limited mixtures between glycolipids and phospholipids[4], excellent quantitative recoveries in terms of dry weight, hexose[2], phosphorus[2], and nitrogen[2] were achieved (Table 1). This quantitative result provides a possibility for a more reliable comparison of absolute amounts of these separate constituents in both human and animal brain preparations.

Fig. 1 shows that fractions III–VI are completely phosphorus-free, yet high in content of hexose. That these are distinct fractions is demonstrated: (1) by the fact that each fraction is exhaustively removed from the column by its particular solvent mixture

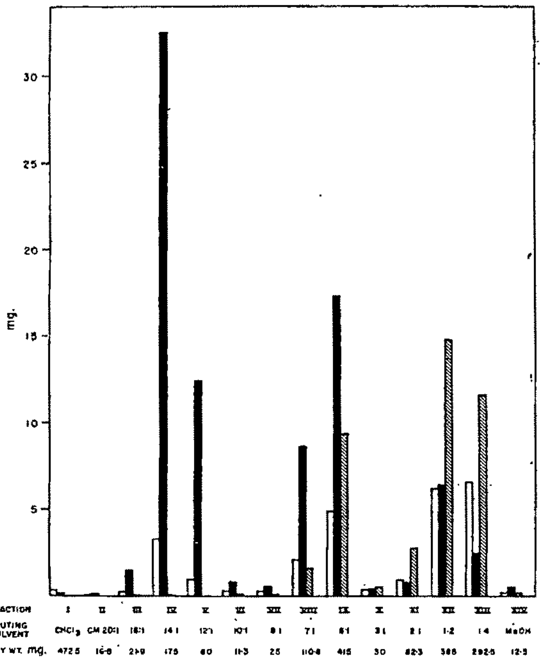

Fig. 1. Stepwise quantitative elution of brain glycolipids. Nitrogen, ☐ ; hexose, ■ ; phosphorus, shaded

until no further dry weight is obtained ; (2) the nitrogen percentage compositions as well as those of hexose differ appreciably in each of these fractions ; (3) these fractions can be distinguished by further partition in terms of their solubility in chloroform – methanol (2 : 1) at 4° C. Thus, for example, fractions IV and V under these conditions both yield precipitates with concentrations of nitrogen (1·73 per cent) and hexose (21·3 per cent) suggesting a cerebroside ; but the remaining supernatants differ markedly in fractions IV and V ; thus the material soluble in cold chloroform – methanol in fraction IV contains 1·8 per cent nitrogen, 22·4 per cent hexose, whereas the material soluble in fraction V contains 1·5 per cent nitrogen, 14·3 per cent hexose. Similar observations apply to each of the other fractions shown in Fig. 1 which contain hexose. Therefore, with respect to elution behaviour, total percentage composition, and composition of sub-fractions, the fourteen major fractions collected by the stepwise procedure described are distinctive.

When all the fourteen fractions obtained were examined for their content of neuraminic acid, this substance was found in only one of the fractions, fraction XII. That this represents brain ganglioside which has not (quantitatively) passed into the upper phase during the preliminary separation is suggested by the fact that purified brain ganglioside[6] was found to be eluted only at this stage when tested by itself on the identical silicic acid column. Thus, at chloroform – methanol ratios of 1 : 1, 1 : 1·5 and 1 : 2, respectively, brain ganglioside is obtained quantitatively. It is of interest to note that each of these three sub-fractions obtained from purified brain ganglioside shows varying concentrations of neuraminic acid and hexosamine. This variation would be in accord with the previous observation in this Laboratory that our preparation of brain ganglioside contains more than one immunochemically distinct substance[7], despite the fact that it demonstrates electrophoretic and ultracentrifugal homogeneity and homogeneity in several solvent systems. It must be considered, however, that despite the apparently non-traumatic nature of the silicic acid chromatography employed, partial degradation of a unitary brain ganglioside material might have occurred. In the case of more harsh solvent procedures utilized by others, in one case[8] acidic solvents known to promote degradation were utilized, and in another case[9] no fraction or sub-fraction of 'brain ganglioside' was obtained with concentration of carbohydrates equal to that of the purified brain ganglioside prepared in this laboratory. While there is no evidence that silicic acid chromatography as used here results in actual degradation in terms of neuraminic acid and hexosamine (recovery 104 and 105 per cent, respectively), the possibility that intramacromolecular disjunction occurred in such a way as to produce fragments with varying relative concentrations of neuraminic acid and hexosamine cannot as yet be ruled out.

Table 1. QUANTITATIVE RECOVERY OF DRY WEIGHT, NITROGEN, HEXOSE AND PHOSPHORUS IN STEPWISE ELUTION OF BRAIN GLYCOLIPIDS FROM SILICIC ACID COLUMNS

Constituent	Type of brain	Amount added to column (mgm.)	Amount recovered (mgm.)	Percentage recovery
Dry weight	Bovine	2000	2088·9	104·4
	Bovine	2000	2113·6	105·7
	Human	2000	2239·8	112·0
Nitrogen	Bovine	26·4	29·3	111·1
	Bovine	26·4	26·7	101·0
	Human	27·3	30·2	110·7
Hexose	Bovine	81·8	82·2	100·4
	Bovine	81·8	84·7	103·5
	Human	81·5	80·2	98·4
Phosphorus	Bovine	42·7	41·1	96·2
	Bovine	42·7	40·9	95·9
	Human	51·8	50·5	97·4

The presence of amino-acids has been tested for, both in the unhydrolysed and in the hydrolysed fractions obtained from the stepwise chromatography of lower-phase material. The combined precipitates obtained from fractions IV and V show the presence of amino-acids before hydrolysis to the extent of 0·17 per cent; this is increased by hydrolysis with 6 *N* hydrochloric acid for 36 hr. to 0·94 per cent. The filtrates show the presence of 0·13 and 0·80 per cent in the unhydrolysed fractions IV and V, and 1·5 and 1·74 per cent in the hydrolysed samples respectively. The presence of bound amino-acids in at least some of these glycolipid fractions of brain must therefore be considered as in the case of the *Drosophila* lipids[10], and is being further investigated.

The stepwise silicic acid chromatography method described therefore provides a quantitative means of separating, accounting for, and comparing individual glycolipid and phospholipid fractions from mammalian brain. The application of these quantitative methods to human brain specimens has been accomplished with the same yields (Table 1) and will be reported in detail elsewhere. These methods thus provide an opportunity of comparing quantitatively the presence of individual glycolipid fractions in individual brain specimens.

These investigations have been supported by Grant No. *M*-2095 from the United States Public Health Service.

This investigation was carried out during the tenure of a postdoctoral fellowship from the National

Institute of Mental Health, United States Public Health Service (L. A. F.).

2. Hot Methanol Extraction of Human Brain Aminoglycolipids

THE term 'aminoglycolipids' is suggested here to include the family of substances the basic constituents of which are glycolipid in nature, and the additional constituents of which include some amino-carrying components such as a hexosamine or neuraminic acid and its derivatives, or amino-acids, or any combination of these three classes of substances. This group of substances would therefore include cerebroside-like substances with extra hexose units per mole of sphingosine[1,2], cerebrosides with extra units of hexose and hexosamine[3] and the above substances with neuraminic acid and/or amino-acids attached[4,5]. The last members of this family, as first isolated[6], were named 'gangliosides'. The addition of these constituents bearing amino-groups is frequently associated with the fact that the complex which is formed bears macromolecular characteristics as determined by non-dialysability and sedimentation values in aqueous ultracentrifugal fields. Although very little is known of the biosynthesis of any of these[7,8], their structural similarities suggest a biosynthetic continuity. Furthermore, attempts to isolate these components by different solvent techniques frequently result in the extraction of protein or lipid substances apparently bound to the aminoglycolipid in either ionic or covalent form, but separable from the aminoglycolipid by a further purification procedure which is almost invariably rather harsh. Structural investigations carried out in this Laboratory[9,10] have led to some clarification of the structure of the macromolecular brain ganglioside of bovine origin and have demonstrated that cerebrosides are clearly structural sub-units of ganglioside[9].

The methods used for the extraction of bovine brain ganglioside have now been applied to human brain specimens obtained at autopsy in 36 mental hospital cases, most of whom were in the eighth and ninth decade of life. Quantitative results were obtained for the yield of 'crude brain ganglioside', neuraminic acid, hexose, hexosamine, nitrogen, and amino-acids, per gm. of whole fresh tissue.

Approximately 100-gm. aliquots of carefully dissected grey and white matter were homogenized for 2 min. with 5 volumes of methanol at room temperature. The homogenate was heated to the boiling point and quickly filtered through a pre-warmed Buchner funnel, the filtrate placed in the cold for 48 hr., the precipitate which formed separated by filtration in the cold and then taken up at room temperature with chloroform – methanol (2 : 1). This 'precipitate fraction' was analysed for dry weight and neuraminic acid, then partitioned as with the preparation of bovine brain ganglioside[10] with distilled water 12 per cent by volume, the upper phase removed and the lower phase again washed with 6 per cent water. The combined upper phases were designated 'crude brain ganglioside', taken to dryness by vacuum distillation at 55–60° C., taken up quantitatively with water and dialysed exhaustively at 4° C. in pre-washed 'Cellophane' bags against a double volume of water. After less than 0·5 mgm. was obtained in the outer water (usually by the tenth change) the dialysed material was collected quantitatively with water washings and analysed for its content of dry weight, nitrogen, neuraminic acid, hexosamine, and hexose[10]. Aliquots of this 'crude brain ganglioside' were hydrolysed with varying concentrations of acid and varying time to determine the maximum yield of hexosamine. This was found constantly to be obtained by 15 hr. of hydrolysis with *N* hydrochloric acid in a sealed tube at 100° C. in 6 hydrolysis curves (½, 1, 3, 5, 7, 9, 12 15, 24, 36, and 48 hr.) on five different brains. Then hexosamine was determined as a routine in this manner. Another aliquot of 'crude brain ganglioside' was hydrolysed with 6 *N* hydrochloric acid in sealed tubes at 100° C. for 1, 3, 6, 12, 24, and 36 hr. and the hydrolysate was tested quantitatively for free amino-nitrogen[11] and examined by paper chromatography[12]. Semi-quantitative paper chromatography of amino-acids present in this dialysed material after 36 hr. of hydrolysis demonstrated the presence of serine, glycine, glutamic acid, aspartic acid, cysteic acid, arginine, alanine, *iso*leucine, leucine, lysine, and one as yet unidentified amino-acid quantitatively present in approximately the order named. These findings are similar in some respects, but quite different in others from those described for a similar preparation from ox brain[5]. Thus threonine, phenylalanine, histidine, and valine were absent in our preparation, and serine was present in excess of glutamic acid. With short-term (1 and 3 hr.) hydrolyses, some indication was obtained of the order of release of these amino-acids. Glycine and serine were almost completely released in 1 hr., the amounts of arginine, glutamic acid, aspartic acid were present in approximately one-half their total, together with only traces of the other amino-acids mentioned here.

Table 1 shows some of the characteristic values for the carbohydrate constituents obtained to date. It may be noted that the crude brain ganglioside material obtained by identical extraction procedures in different brains analyses differently in each case, not only with regard to the absolute amounts of neuraminic acid, hexose, and hexosamine obtained per gram of whole tissue, but also with regard to their relative ratios. There is a higher content of hexosamine with reference to neuraminic acid in human brain and usually still higher content of hexose. It is therefore clear that this 'crude brain ganglioside fraction' derived from human brain by hot alcoholic extraction contains related non-dialysable aminoglycolipids other than bovine brain ganglioside as classically defined in terms of percentage constituents by Klenk[6] and structurally clarified in our own investigations[10]. Thus, our bovine brain ganglioside contains, in ash-free form, 30 per cent neuraminic acid, 24 per cent hexose and 10 per cent hexosamine, and the salt form of bovine brain ganglioside contains approximately

Table 1. Yield of 'Crude Brain Ganglioside' and Constituent Neuraminic Acid, Hexosamine and Hexose in 36 Individual Human Brain Specimens

	'Crude brain ganglio-side' (mgm./gm. whole tissue)	Neur-aminic acid (μgm./gm. whole tissue)	Hexos-amine (μgm./gm. whole tissue)	Hexose (μgm./gm. whole tissue)	Nitrogen (per cent)
Grey matter					
Mean	2·20	248·3	143·1	247·9	1·54
Range	0·44–4·50	105–406	29–284	54–512	0·5–2·8
White matter					
Mean	2·10	66·0	48·0	179·0	2·2
Range	0·13–7·3	9·7–191	3·2–124	31–419	1·1–5·0

26, 20·8, and 8·7 per cent respectively of these three constituents. In no case so far analysed did these ratios hold for the material examined. There must therefore be either a different type of ganglioside in the human brain, or a ganglioside similar to that found in bovine brain is present, but considerably contaminated by substances richer in hexose and hexosamine which are non-dialysable and partitioned to this point along with the hypothetical human brain ganglioside.

In the purification of bovine brain ganglioside, the crude material is repartitioned four of five times between chloroform - methanol and water[10]. When crude brain ganglioside material, after isolation from brains Nos. 63, 65, 69, 70, 72, was combined and further repartitioned four times, the lower phase contained some 9 or 10 per cent of the dry weight of the fraction at each stage and the material in the lower phase contained increasing amounts of both neuraminic acid and hexose. Thus, the lower phase from the second, third, and fourth repartition contained respectively hexose 6·7, 8·9, 12·4 per cent and neuraminic acid 4·6, 10·8 and 13·0 per cent. The upper-phase material remaining after the fourth repartition now contained 16 per cent hexose and 22·3 per cent neuraminic acid thus approaching the theoretical concentrations and molar ratios of these substances observed in purified brain ganglioside. Further purification and structural investigations on larger quantities of this material are in progress.

It is clear from these results that the classical brain ganglioside is only one of a group of non-dialysable aminoglycolipids which can be extracted from human brain grey matter by means of the hot-methanol method described; that the other substances so extracted are quite rich in hexose, hexosamine, and neuraminic acid; and that these substances can be separated from each other. It would therefore appear that a large family of related substances exists in human brain with varying amounts of the structural constituents described here, in macromolecular association, which might be grouped under the term 'aminoglycolipids'. From a practical point of view, it is clear from our results that neither hexose, hexosamine, neuraminic acid, nor any combination of these three components isolated by the above techniques can be used to extrapolate the concentration of brain ganglioside[13]. The next communication demonstrates that, in addition to the heterogeneity of these materials isolated with alcoholic solvents, the yield in terms of both neuraminic acid and hexosamine is only one-third to one-fifth of the total which can be demonstrated by the emulsion-fractionation procedure developed.

These investigations have been supported by Grant No. *M*-2095 from the United States Public Health Service.

3. Quantitative Separation and Determination of Brain Glycoproteins, Neuraminic Acid, Hexosamine, and Hexoses by Means of Whole Tissue Emulsion-Fractionation

THE demonstration that there is a family of non-dialysable aminoglycolipids in brain related to classical brain ganglioside[1,2] but differing from it in terms of the relatively greater content of hexosamine and hexose (previous communication) has made it necessary to devise suitable methods whereby all these substances may be extracted quantitatively, further purified, and studied in terms of their relative concentrations in individual brain specimens. In addition, these observations have raised the question of the nature of the macromolecular organization of these constituents *in situ*. This organization would appear to be well worth studying because, on one hand, electron microscopic observations may approach visualization of these complexes and, on the other hand, better understanding of such biological problems as the properties of living cell membranes in terms of receptor and transport functions appear to require better structural definition of what might be called the molecular geometry of membrane components.

Thus, for example, the isolation of brain ganglioside, which has been shown in this Laboratory to have physiological properties suggesting membrane receptor and transport functions[3-6], has generally been accomplished by means of hot or cold organic solvent mixtures. In one method of extraction[1], this aminoglycolipid is obtained in crystalline form and without the presence of amino-acids; in a second method[2], essentially the same glycolipid is obtained with further macromolecular properties, but still without amino-acid constituents; and in a third method of extraction, the glycolipid is obtained with macromolecular characteristics and with the presence of attached amino-acid constituents[7]. These experiments suggest that it would be fruitful to approach these macromolecular aminoglycolipids from the 'protein point of view'. That is, where harsh organic solvents might dissociate protein – aminoglycolipid complexes, leaving only a few amino-acids tied to the aminoglycolipid (previous communication, and ref. 7), solvent methods which are directed towards isolation of the proteins of brain might accomplish the isolation of the intact protein and carry with the protein the glycolipid constituents.

A qualitative method for approaching this problem has been developed in recent work in this Laboratory and will be reported here briefly, and elsewhere more extensively. By means of the emulsion-fractionation method to be described, essentially all the proteins of the brain are separated into nine primary fractions in a manner which does not necessitate the discarding of large amounts of protein as insoluble[8], and which permits further fractionation to be undertaken. Furthermore, new results for the total concentrations of brain neuraminic acid, hexosamine, and hexose are thereby obtained.

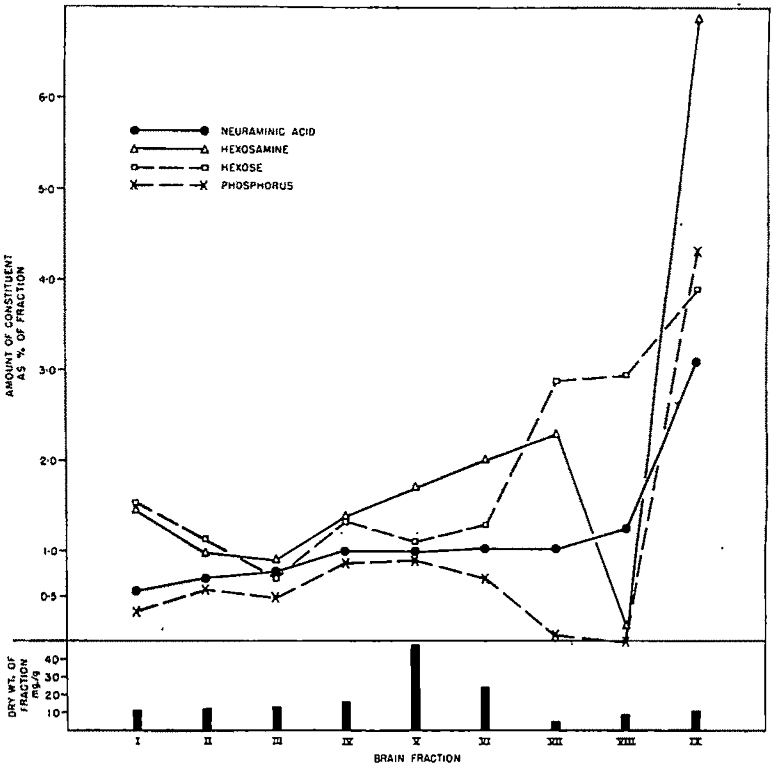

Fig. 1. Emulsion fractionation of human brain grey matter

Freshly autopsied human and bovine brains were immediately stripped of investing meninges and blood vessels and grey and white matter carefully dissected from particular anatomical areas. While the results reported will be on the basis of 5-gm. aliquots of dissected grey matter, all the procedure can be carried out with 1 gm. or less of whole tissue and has been done with white matter as well. 5 gm. of brain tissue is homogenized in a Waring blendor with 180 c.c. of distilled water for exactly 5 min. The temperature at the end of homogenization is 32-33° C. The balance of the procedure is carried out at room temperature (25° C.). (The entire procedure is also effectively carried out at 0°.) The rather stable emulsion which is formed is transferred with 3 c.c. water washing to centrifuge bottles and centrifuged at 1,300 r.p.m. (225 *g*) for exactly 10 min. The precipitate which results is denoted fraction I. The supernatant is carefully decanted, methanol is added to the extent of 50 per cent by volume, the solution is mixed and immediately centrifuged for exactly 10 min. The precipitate which results is denoted fraction II. To the supernatant, which has been carefully decanted, is added sufficient methanol to reach an equivalent of one volume relative to the original volume of emulsion. The solution is immediately centrifuged as above and the precipitate (fraction III) is obtained. By successive addition to the supernatant at each stage of aliquots of methanol so that the final solution contains 1·5, 2, 2·5, 3, and 3·5 volumes of methanol relative to the original volume of emulsion, precipitates are obtained at each stage which are successively denoted fractions IV – VIII. The supernatant remaining after precipitation of fraction VIII with 3·5 volumes of methanol, which is now water-clear and which no longer yields appreciable further precipitate on the addition of further volumes of methanol, is taken to dryness by vacuum distillation at 55–60° C. and is designated fraction IX. Each of these nine fractions is quantitatively taken up in distilled water to form a 1–10 mgm. per c.c. suspension. This suspension can then be analysed, taken up in buffers, or further partitioned into dialysable and non-dialysable constituents. For this further partition the suspension is transferred quantitatively with distilled water to pre-washed 'Cellophane' bags and dialysed at 4° C. against equal volumes of distilled water if collection and further study of the dialysable material is desirable, or against 10- to 20-fold volumes of distilled water for more rapid isolation of non-dialysable components when the dialysable components are not sought.

Fig. 1 summarizes a typical emulsion-fractionation procedure in terms of 5 gm. of grey matter. The dry weight is shown in the bar graph and the percentage of phosphorus, neuraminic acid, hexose, and hexosamine is shown for each of the nine dialysed fractions. The analytical methods used are as given in the previous two communications. It may be seen that each of the nine fractions is distinguished not only in terms of its precipitability at different concentrations of methanol, but also in terms of its percentage composition of the above constituents. Thus, the early fractions are poor in phospholipid, relatively rich in bound hexose, and relatively poor in bound neuraminic acid. With increasing concentration of methanol, non-dialysable complexes are precipitated with varying, but generally increasing concentrations of neuraminic acid, hexosamine, and hexose. The concentrations of nitrogen in fractions I–IX respectively are 4·6, 5·2, 4·8, 13·2, 8·1, 6·8, 6·1, 5·2 and 14·2 per cent. The concentration of bound hexose increases markedly in the last three fractions. Phosphorus is low in fractions VII and VIII, and the concentrations of nitrogen, hexose, hexosamine, and neuraminic acid in fractions

VII, VIII and IX suggest relatively purer glycoprotein preparations. Recovery in terms of dry weight of the unfractionated emulsion is 94–98 per cent.

Each of these fractions can be fractionated further by virtue of solubility in different buffer systems or, as illustrated here, by treatment with mixed solvent systems. Thus, for example, in one brain when fraction IX was partitioned between the three-solvent system of chloroform–water–methanol[6], whereas the lower phase contains lipid material with only 3·6 per cent nitrogen, 0·19 per cent neuraminic acid, and 1·6 per cent hexose, the first two upper phases which are obtained combined contain glycoprotein CIX*a* with a nitrogen content of 11·8 per cent, neuraminic acid content of 1·7 per cent and hexose content of 4·7 per cent. In other brain specimens CIX*a* contained as much as 4·1 per cent neuraminic acid and 8·0 per cent hexose.

The above emulsion-fractionation method thus permits the quantitative fractionation of all brain proteins into nine primary fractions in association with native lipids in the form of emulsions (not true solutions, with the exception of fraction IX), in which the protein components appear to be protected from gross denaturation by the presence of the associated lipids (possibly the same lipids as those *in situ*) and by the absence of harsh organic solvents at the preliminary separation stages. This procedure, in contrast to others[8], does not produce masses of insoluble denatured protein amounting to 50–90 per cent of the total protein content of brain.

The yield of grey matter neuraminic acid by emulsion-fractionation (1·7–1·8 mgm./gm. whole tissue) is in excess of that obtained with chloroform–methanol[10] and with hot methanol techniques (previous communication). The partition of fractions CIV, CV and CIX by chloroform–methanol–water demonstrates that much of the neuraminic acid of brain previously assumed to be part of brain ganglioside is in fact part of other aminoglycolipids and glycoproteins.

Similarly, the yield of hexosamine from human grey matter alone by emulsion-fractionation (2·3–2·7 mgm./gm. fresh tissue) is two or three times that previously reported[12] for whole bovine brain. In addition to higher total yield, the disadvantage of the multiple organic solvent and water extractions for hexosamine[12] (which left 62 per cent of the recovered brain hexosamine in the insoluble residue) is overcome.

Both hexosamine and neuraminic acid are seen here in association with several brain glycoprotein fractions, which vary in the ratios of their content of each of these constituents. The total concentration of grey matter hexosamine is found to be in excess of that of neuraminic acid (whereas in purified brain ganglioside the reverse is true, that is, neuraminic acid being present in threefold excess of hexosamine by weight). Therefore, attempts to estimate brain ganglioside on the basis of the amounts of total neuraminic acid and/or hexosamine which can be extracted[11,13] cannot be considered valid, and brain ganglioside can only be determined at present by isolation of the material which has the characteristic ratios of these constituents. The presence of this non-ganglioside brain hexosamine and neuraminic acid is partially accounted for by brain glycoproteins.

The yield of grey matter hexose by emulsion-fractionation is 2·2–6·0 mgm./gm. fresh tissue. Whereas essentially all the neuraminic acid and hexosamine is non-dialysable, 16–40 per cent of grey matter hexose is dialysable, that is, approximately 1 mgm./gm. fresh tissue, a figure in good agreement with those given previously for 'labile' brain glucose[9].

There is evidence of variation between specimens of brain from different individuals in the total amounts of each constituent in different fractions, a finding of interest in relation to the high degree of chemical individuality observed in this Laboratory in work on the same constituents in another compartment of the nervous system, namely, the glycoproteins of human cerebrospinal fluid[14–16].

The further isolation of individual brain glycoprotein components from each of the nine primary fractions is now in progress and these are denoted CI*a*, CI*b*, etc. for cortical grey matter glycoproteins, and WI*a*, WI*b*, etc. for white matter glycoproteins. Antisera have been prepared in rabbits to fractions CIV and CV and the histological localization of these substances observed in human brain sections by the fluorescent antibody technique, as done in the case of brain ganglioside[6]. Preliminary results suggest a predominantly glial localization of CV and a predominantly neuronal localization of CIV, and the method is being extended to the other seven fractions.

The emulsion fractionation method described provides a simpler, yet more quantitative means of estimating brain neuraminic acid, hexosamine, and hexose in both normal and pathological specimens of brain than methods previously available; permits the quantitative separation and study of nine primary individual brain glycoprotein fractions which differ in their chemical composition; and permits the further separation of sub-fractions from each of the primary ones. In addition, because of the relative mildness of the procedure, it offers an opportunity for enzymatic studies on one hand, and for histological studies on the other, and therefore may be useful in approaching structure-function problems with reference to glycoproteins and aminoglycolipids in the nervous system.

These investigations have been supported by grant No. *M*-2095 from the United States Public Health Service.

ASTROPHYSICS

Terrestrial Accretion from the Solar Wind

IN order to account for the observed motions of comet tails, Biermann[1] conceived that the solar corona emits suprathermal particles at the rate of 10^{14}–10^{15} gm./sec. Since this material is evidently supplied by the Sun itself, this seems to imply that Unno's observation[2] of turbulent motions in the chromosphere and lower corona corresponds in reality to a systematic radial emission of particles from the Sun, the velocity v of which is related to the hydrogen ion concentration n by the relation $v = Bn^{-1/4}$, where $B = 8 \times 10^8$ (cm.)$^{1/4}$ sec.$^{-1}$. This empirical relation is of the same form as Parker's magneto-hydrodynamical velocity-amplitude relation[3,4], $v(r) = v_0(n_0/n_r)^{1/4}$, the applicability of which is certainly not restricted to the chromosphere. Thus the possibility of extrapolating Unno's result to interplanetary space deserves further consideration.

Application of the equation of continuity to this flux yields $nr^2v =$ constant, r being the radial distance from the centre of the Sun. Combining this with Unno's relation, one obtains $n \propto r^{-8/3}$ and $v = Kr^{2/3}$, where K is a constant. Writing $v = dr/dt$ and integrating the resulting equation, the transit time of a proton in the solar wind from the solar surface at r_0 to the orbit of the Earth at r_1 is $t = 3(r_1{}^{1/3} - r_0{}^{1/3})/K$, and since $K = v_1/r_1{}^{2/3}$, we obtain:

$$v_1 = \frac{3r_1}{t}\left[1 - \left(\frac{r_0}{r_1}\right)^{1/3}\right]$$

Transit time measurements show that t is about one day, hence $v_1 = 4{\cdot}33 \times 10^8$ cm./sec. and $n_1 = (B/v_1)^4 = 11{\cdot}65$ protons/cm.^{3} at the orbit of the Earth.

This result is compatible with the recent findings of Pope[5] (from a study of whistlers) and of Kupperian[5] (from Lyman α observations). It is also reasonably compatible with van de Hulst's estimate of 3×10^7 electrons/cm.^{3} at a distance $r_c = 10^{11}$ cm. from the centre of the Sun, for which the present theory gives a concentration $n_c = n_1(r_1/r_c)^{8/3} = 0{\cdot}74 \times 10^7$ protons/cm.^{3}. On the other hand, Biermann suggests that at the orbit of the Earth, $n_1 = 500$ protons/cm.^{3} on magnetically quiet days, and quotes the outward radial velocity v_1 as ranging from 500 to 1,500 km./sec. It would seem that Biermann's n_1 is too high, his v_1 too low; the same dynamical effects on comet tails, dependent on $n_1v_1{}^2$, would result from the extrapolation of Unno's relation. Denoting the proton mass by m_H, the rate of emission of hydrogen by the Sun is then $4\pi r_1{}^2 n_1 m_H v_1 = 2{\cdot}4 \times 10^{13}$ gm./sec.

Moreover, the energy of a proton travelling at $4{\cdot}3 \times 10^8$ cm./sec. is about 100 keV., and assuming a localized equipartition of proton and electron energy within the outer Van Allen radiation belt, the mean energy of the electrons in this region must be 50 keV., in accord with Van Allen's results from satellite data. Electrons of this energy have a velocity $v = 1{\cdot}24 \times 10^{10}$ cm./sec., yielding an electron flux $n_1v = 1{\cdot}44 \times 10^{11}$/cm.^{2} sec., again in accord with recent observations.

The rate of accretion of hydrogen by the Earth from the solar wind is of great interest. The Earth must have been exposed to this flux throughout its estimated age, $T = 3{\cdot}3 \times 10^9$ years or $1{\cdot}04 \times 10^{17}$ sec. Assuming that the magnetic field of the Earth remains effective in capturing protons and electrons up to a distance $r_m = 12{\cdot}3$ Earth radii from the Earth's centre, as suggested by the onset of field disturbances at this distance[5], the total mass of hydrogen accreted by the Earth throughout its existence is $\pi r_m{}^2 n_1 m_H v_1 T = 1{\cdot}70 \times 10^{23}$ gm. Complete oxidation of this hydrogen would yield $1{\cdot}53 \times 10^{24}$ gm. of water, in close accord with the known ocean mass[6] of $1{\cdot}42 \times 10^{24}$ gm. This remarkable result indicates that the seas must have been formed gradually by accretion of solar hydrogen at the rate of about 1·5 tons/sec., and that this process is still taking place.

Finally, the presence of about 1 part of deuterium in 6,700 of hydrogen in sea-water is in reasonable agreement with Severnyi's estimate[7] of the relative abundance of deuterium at the solar surface, especially when allowance is made for the possibility of isotopic fractionation during the transfer process. This implies in turn a rate of emission of deuterium of $3{\cdot}5 \times 10^{10}$ deuterium atoms/cm.^{2} sec. from the solar surface. The question of the origin of this deuterium remains one of the greatest unsolved problems of solar physics.

GEOPHYSICS

Measurement of Positive-Ion Density in the Ionosphere by Sounding Rocket

Two sounding rockets, *Kappa*-VIII-3 and -4, a detailed account of which will be published elsewhere, were fired at 15h. 32m. 00s. September 22 and 20h. 25m. 00s. September 26, 1960, in order to observe the vertical profiles of positive ion density in the ionosphere. The launching site was the Akita Rocket Range in Japan, of which the geographical co-ordinates are lat. 39° 34′ N. and long. 140° 04′ E. Simultaneous observation of the ionosphere in vertical incidence was made at the Akita Radio Wave Observatory of the Radio Research Laboratories, geographical co-ordinates lat. 39° 44′ N. and long. 140° 08′ E.

Each rocket was provided with the spherical Langmuir probe in the nose cone, which was split vertically into two parts at an altitude of about 60 km. to expose the ion probe to space.

The probe installed in the rocket for the day-time flight was a meshed spherical cage of molybdenum

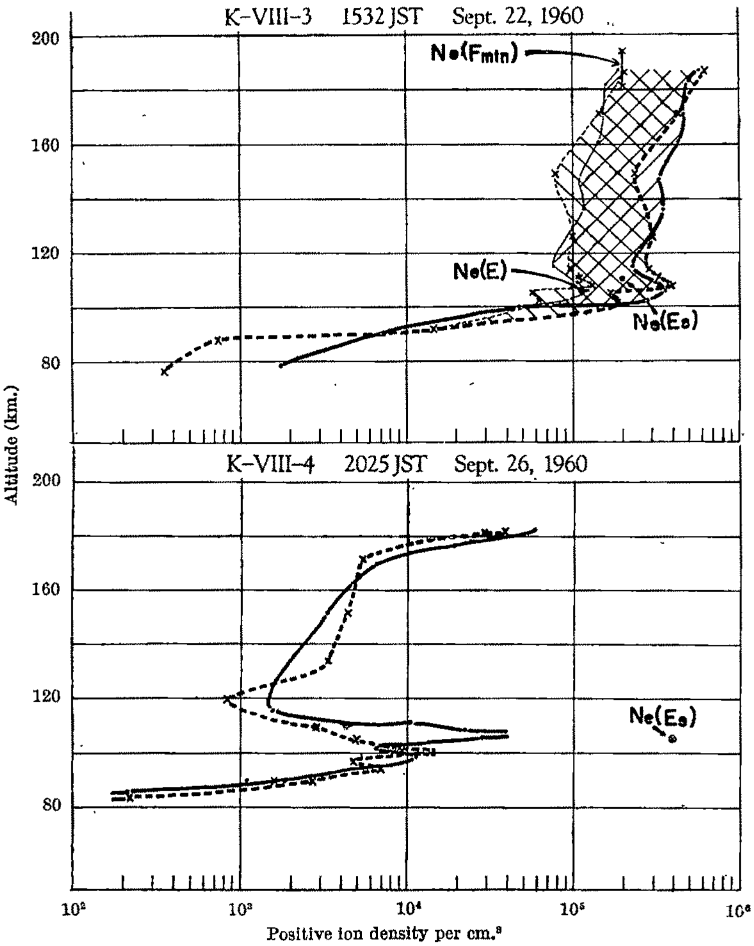

Fig. 1. Plots of ion density as a function of altitude. Observations during ascent, ●—●; during descent, ×---×. *Ne(E)* is the electron density of *E*-layer; *Ne(Es)* that of *Es*-layer and *Ne(Fmin.)* is that of lowest part of *F* layer. These values are calculated from the ionograms shown in Fig. 2

wire of 0·3 mm. diameter and welded electrically. This form of probe was used so as to eliminate the effect of the strong photoelectron emission from the surface of the probe excited by the ultraviolet component of solar radiation in the upper atmosphere. This effect has been found to cause serious disturbance in the measurement of ion current[1]. The spacing of the wires was such that the ion sheath formed around the probe was perfectly spherical, and observations in the region of low ion density in the ionosphere were reliable. The probe has a diameter of 2·0 cm. and is gold-plated. The probe for the night-time flight was the usual gold-plated spherical shell but of the same diameter.

Each probe was fastened at the top of a long tapered metal rod of 65 cm. to avoid deformation of the ion sheath around the probe due to the rocket body. The metal rod, made of duralumin, was coated with silicone resin to insulate the probe electrically from the environment. When the probe system was immersed in plasma, the ion current in the probe system would flow only from the spherical probe, and calculations of the ion density would be quite trustworthy.

The flights were successful and complete records were obtained throughout both ascent and descent. In this communication, we describe preliminary results analysed from measurements of ion densities by sounding rocket. A complete analysis of the observations will be reported elsewhere.

Fig. 1 shows the profiles of the positive ion density calculated from the observed probe currents at a probe potential of about 20 V. against the body of the rocket. The values of electron temperature and ion mass in the ionosphere, which are essential for calculation of the ion density from the probe current, were taken from Yonezawa's paper[2]. Depending on the behaviour of ions in the ion sheath, different methods of calculation were adopted for various altitudes of the rocket, namely, regions of many collisions, one collision and orbital motion in the sheath. In the orbital region, only a portion of the ions gathered on the probe can collide with the meshed spherical cage. The minimum correction factor, that is, collection probability, is determined here from the geometrical configuration of the probe; the maximum correction factor is believed to be

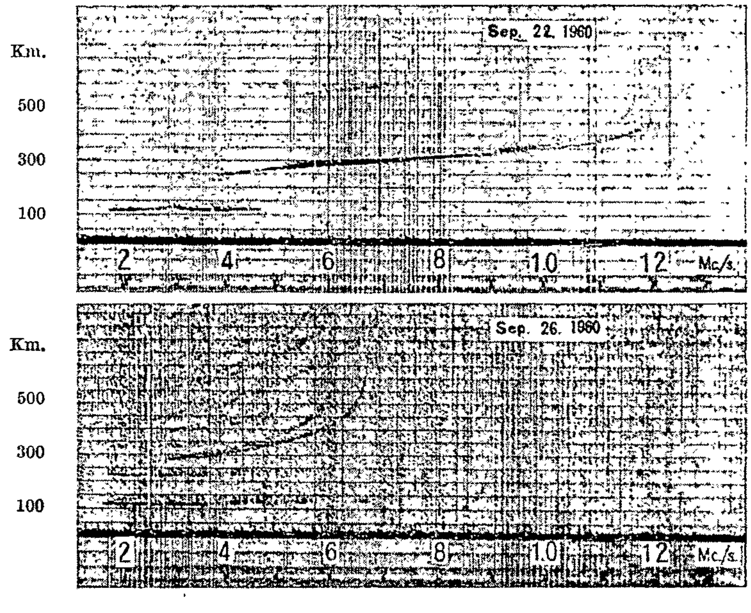

Fig. 2. Ionograms obtained at the Akita Radio Wave Observatory

about three times as great. Hence the results shown by the hatched area in Fig. 1 indicate the probable maximum values of the ion density.

The *h′–f* curves obtained by vertical incidence observation of the ionosphere are shown in Fig. 2. Numerical values of the electron density at the true height scaled from these *h′–f* curves are plotted in Fig. 1 in order to compare the ion and electron densities.

It is remarkable that the records both in the day-time and at night during the ascents show close agreement with those during the descents. Also, the numerical values of electron density scaled from *h′–f* records agree fairly well with those for ion density in the measurements by sounding rocket. It is interesting that the night measurements indicate remarkably thin layers of ion density in space of very low density, corresponding to the sporadic *E* layer observed in *h′–f* observations. Furthermore, it is noticeable that ions exist from the rather low altitude of 60 km. in the ionosphere during day-time.

We are indebted to the Institute of Industrial Science in the University of Tokyo for firing the sounding rocket of *Kappa* VIII, and we thank Prof. K. Maeda for his encouragement.

Lavas from an Abyssal Hill on the Floor of the North Atlantic Ocean

IN May 1958, during a cruise of R.R.S. *Discovery II*, underwater photographs by Dr. A. S. Laughton revealed rock outcrops and talus slopes on a small abyssal hill which rises 200 m. from the Iberia Abyssal Plain to a summit depth of 4,960 m. and is situated 300 miles north-west of Lisbon at 41° 21′ N., 14° 28′ W. Dredging produced a large collection of rocks from the hill. This collection is significant because it is believed to be unique[1] and may represent material from an outcrop of Hill's "seismic Layer 2"[2]. The petrographic homogeneity of the collection indicates that the dredged stones were not erratics: four are bedded palagonitic vitric-tuffs and four are granitic erratics, but all the remaining three hundred and fifty-four are highly altered vesicular basalt. Some characteristically shaped fragments of pillow lavas contain relatively fresh material, including a few grams of a tachylitic margin which has escaped palagonitization. The magma appears to have been a porphyritic bytownite-rich augite-basalt without olivine. Extensive alteration, believed hydrothermal, has produced relatively soft rocks from the original lavas. In the course of alteration there was significant oxidation of iron; loss of silica, lime and magnesia; gain in potash; manganous oxide was redistributed as pelagite ('manganese') within the rocks. Autoradiographs show that this secondary pelagite is quite strongly radioactive and accounts for the unexpectedly high radioactivity (13 p.p.m. equivalent-U_3O_8, an amount that would be normal for a granite) measured in bulk samples of the altered lavas. The 'manganese' encrusting the stones (visible in Fig. 3) is also quite strongly radioactive (about 50 p.p.m. *e*–U_3O_8). Probably, both the pelagite within the stones and that in the encrustation were deposited after solution in seawater and acquired its radioactivity from the sea. The available evidence does not suggest that the original basaltic magma was unduly radioactive.

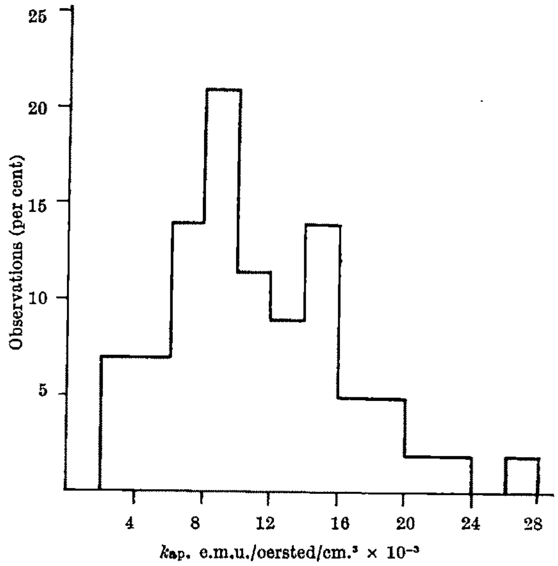

Fig. 1. Histogram showing distribution of apparent susceptibility, $k_{ap.} = \frac{I + kH}{H}$, in 43 specimens of lava. Number of observations (per cent) falling in intervals of 2 × 10^3. *I* is intensity of remanent magnetization, *k* the susceptibility, and *H* is 0·437 oersted

Data presented in Fig. 1 indicate that the altered lavas are slightly less magnetic than normal basalts although their susceptibility (median value 5 × 10^{-4} e.m.u./oersted/cm.³) and remanent magnetization (median 5 × 10^{-3} e.m.u./cm.³) lie within the known range of variation for basalts.

Fig. 2 shows results of determinations of compressional wave velocity in the altered lavas. Velocities were measured at room temperature and pressure, parallel to a uniaxial compressive stress of a few tens of atmospheres. Variation of velocity with hydrostatic compacting pressure was measured in six jacketed saturated specimens under differential confining pressures of 1–1,000 kgm./cm.² using apparatus similar to that of Wylie *et al.*[3]. At 1,000 kgm./cm.² the three softer specimens had become crushed and compaction was complete in the others. The maximum increase in velocity observed was 30 per cent. This result, and those of Fig. 2, indicate that the seismic velocity obtaining in these altered lavas under the sea bed would be in, or below, the lower part of the range of velocities (4–6 km./sec.) ascribed to Layer 2. It is suggested that lava flows

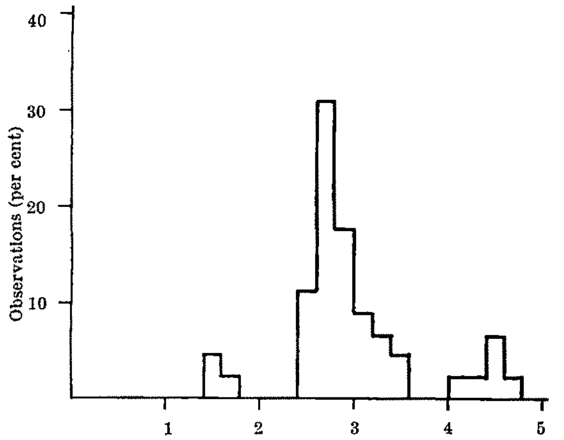

Fig. 2. Histogram showing distribution of compressional wave velocities measured in screw press in 45 water-saturated cylinders of lava. Number of observations (per cent) in intervals of 0·2 km./sec.

of *altered* basalt could be common in Layer 2 under the oceans.

The collection includes twenty large slabs thought to be pieces of the brecciated surface of an outcrop, held together by encrusting 'manganese'. Examination of these slabs (Fig. 3) has suggested details of a weathering process whereby the angular detritus frequently photographed on submarine talus slopes could have been detached from the outcrops. The breccia consists of closely interlocking angular fragments of lava, themselves riddled with cracks lined with dendritic films of pelagite. The wider cracks contain a 'soil' of the clay mineral alteration-products of palagonite and chlorophæite, with occasional calcite and zeolites. It is suggested that the change in volume associated with the formation of these minerals may serve to prise off angular fragments along the line of pre-existing shrinkage cracks.

Grateful acknowledgment is made to Dr. J. C. Swallow and the Director of the National Institute of Oceanography for facilities in R.R.S. *Discovery II* and to Dr. Bowie of the Geological Survey (Atomic Energy Section) for bulk radiometric assays. Part of this work was supported by a studentship from British Petroleum and part by the U.S. Office of Naval Research under a contract with the University of Cambridge.

PHYSICS

An Apparent Paradox in Crystal Structure Analysis

A commonly used test for the correctness of a crystal structure deduced from X-ray diffraction data is to perform a Fourier synthesis using the observed structure amplitudes ($|F_o|$) and the calculated phases (α_c) in the Fourier coefficients (namely $|F_o| \exp i\alpha_c$) and to verify that this diagram gives peaks of the right magnitudes at the assumed positions of atoms and none elsewhere. It was thought worth while examining what would happen if the amplitudes and the phases that are fed in belong to different structures. The tests that were carried out are briefly described here, together with an explanation of the results observed and their relation to the methods of structure analysis.

A series of syntheses were first calculated using the phases (α_c) calculated from the atomic positions of tyrosine hydrochloride[1], but employing (*a*) structure amplitudes that were completely random, (*b*) structure amplitudes which were made equal for all reflexions except for a falling off with ($\sin\theta/\lambda$) corresponding to the unitary structure factor and (*c*) using a set of amplitudes which were made, so far as possible, anti-correlated to the correct values about the mean. In every case, the atomic peaks occurred at the same positions as in the assumed structure from which the phases were calculated.

This result, quantitative details of which will be published elsewhere, confirms the known fact that, particularly for a non-centro-symmetric structure, correct phases are of much greater importance than correct amplitudes in determining the positional co-ordinates of atoms[2]. For example, severe extinction can be tolerated provided that only atomic positions are required.

These tests suggested another possibility, namely, the use of the calculated phases of one crystal and the structure amplitudes of a completely different crystal and seeing what the resultant Fourier synthesis would look like. Fig. 1 (*a*) was obtained in this way. It is the *c* projection of a crystal (symmetry $P2_1$) for which the phases were obtained using the positions of the 13 light atoms in the molecule of tyrosine (as it occurs in tyrosine hydrochloride[1], $a = 11{\cdot}1$ Å., $b = 9{\cdot}0$ Å., $c = 5{\cdot}1$ Å., $\beta = 92°$, $Z = 2$, but without the two chlorine atoms) and the structure amplitudes $|F_o|$ of an imaginary crystal having 6 atoms in its asymmetric unit, but having the same unit cell and the same number of electrons in the unit cell. The positions of these atoms are marked by crosses in Fig. 1. They were taken to have a suitable scattering factor falling off with angle as for a carbon atom, so that the average intensity for both crystals would be exactly the same. Fig. 1 (*b*) is the electron-density diagram obtained by feeding back the data for tyrosine, that is, using both the amplitudes $|F_c|$ and the phases α_c of tyrosine itself. It will be noticed that there is a marked agreement between the two diagrams, and that all the atoms of tyrosine have come out in the first diagram even though the data for structure amplitudes used were of an entirely different crystal. The peak heights which are equal in Fig. 1 (*b*) are, however, very unequal in Fig. 1 (*a*) and traces of new peaks have appeared, one of which is about equal in electron density to one of the tyrosine atoms. Nevertheless, the absence of any semblance of a peak at three of the atomic positions of the structure amplitude data of the crystal used (marked by crosses) is very striking.

The use of a 'difference synthesis' cannot be expected to reveal the atomic positions of these three missing but 'correct' atoms, since for a difference synthesis to be meaningful, F_o and F_c must be very nearly equal in phase. However, Fig. 2 has been calculated using $(|F_o| - |F_c|) \exp i\alpha_c$ as the Fourier coefficients, where $|F_o|$ refers to the six-atom structure and $|F_c|$ to tyrosine. It will be noticed that although, at some of the tyrosine atoms (marked by dots), there is a small negative density, and although three of the X positions still indicate a very small positive density, the other three X atoms still fail to appear. In general, the positive and negative densities do not exceed that of a helium atom anywhere in this diagram.

It appears to be a logical conclusion to make from the above results that, if a Fourier synthesis is made using the amplitudes of the correct structure, but the phases calculated from assumed atomic positions different from these, then the resultant synthesis would contain peaks at the assumed positions, but not necessarily at the correct atomic positions. On the other hand, it is well known that the method of using a series of successive Fourier syntheses often gives the correct structure and in fact converges to it, which is in apparent contradiction with the above statement.

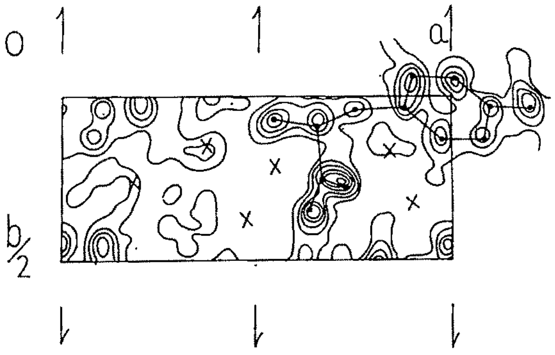

Fig. 1 (*a*)

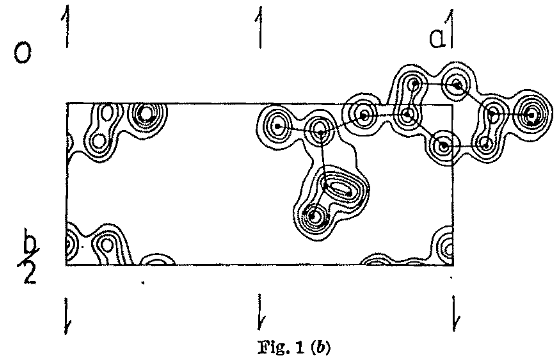

Fig. 1 (*b*)

Fig. 1. *c*-axis projection of the Fourier syntheses using the coefficients (*a*) $|F_o| \exp i\alpha_c$; (*b*) $|F_c| \exp i\alpha_c$, where *o* refers to a hypothetical six-atom structure marked by crosses and *c* refers to the structure of L-tyrosine. Contours are at intervals of 1 e./A.², starting from 1 e./A.²

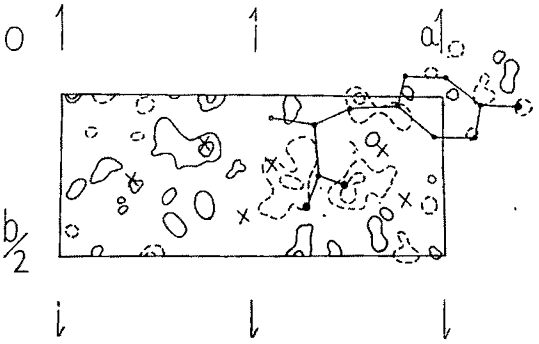

Fig. 2

Fig. 2. The difference Fourier synthesis $(|F_o|-|F_c|) \exp i\alpha_c$. Contours are at intervals of 1 e./A.². Positive contours are shown by continuous lines and negative by broken lines. The zero contour is omitted

There is, however, no real contradiction if it is remembered that in the present test the assumed atomic positions are *all* completely wrong; whereas, in structure analyses which converge, at least some of the atoms of the assumed structure would be at the correct positions (for example, the heavy atoms when such are present). The difference between the two cases is seen most strikingly by applying the general ideas of the de-convolution of the Patterson function and of the modulation of one structure by another developed in our laboratory[3,4]. Thus, the synthesis $|F_A| \exp i\alpha_B$ (where $|F_A|$ is the amplitude corresponding to a structure A and α_B is the phase corresponding to a structure B) is essentially equivalent to the modulations of the Patterson diagram of the structure A with the actual structure B. In this, it is not difficult to show that peaks occur only corresponding to the atomic positions of B and none of A, provided that A and B have no atoms in common. However, if the structures A and B have some atoms (P) in common, then not only would these atoms (P) and the remaining atoms of B come out prominently, but also there would be weaker peaks at the positions of the remaining atoms of A also, their strength being greater the larger the ratio $\sigma_P^2 = \sum_1^P f_j^2 \Big/ \sum_1^A f_j^2$. This last result shows that a necessary condition for peaks to occur at the unknown 'correct' atomic positions is that at least some of the atoms used for calculating the phases must be at correct or nearly correct positions. Since it is the mean contribution to the intensity of these correct atoms that determines the strength of the peaks at the unknown atomic positions, a small number of heavy atoms would serve this purpose equally well. Looked at from the phase point of view, convergence is usually fast in successive refinements in the heavy-atom technique because a large proportion of the phases is already nearly correct at the beginning. In fact, if the value of σ_P^2 is 50 per cent (or about half the phases are correct), a structure would refine rapidly even from very high R values.

As mentioned earlier, a peak has actually appeared at one of the crosses in Fig. 1 (*a*), contrary to the theoretical prediction. We believe this is fortuitous, and this is confirmed by the fact that no peaks at all have developed either in this figure or in the 'difference synthesis' at three other such positions.

It will also be noticed that in Fig. 1 (*a*), the peaks in the assumed positions have re-appeared with unequal peak heights, which itself would indicate that it is not correct, in addition to the large value that occurs for the residual factor (R value).

There has been some discussion in the literature (see, for example, ref. 5) as to whether the R value is really useful in judging the degree of correctness of an assumed structure, particularly since some structures with fairly low R values have turned out to be incorrect. The difficulty in the past has been that experimental errors were often greater than 10 per cent in $F_{\text{obs.}}$, and it was sometimes difficult to distinguish between errors arising from this cause and those arising from a part of the assumed structure being wrong. So also, in some cases, one projection would refine well whereas the others would not, because one set of positional co-ordinates was wrong or because of a wrong choice of origin out of two possibilities. The occurrence of disorder in one direction or of a very anisotropic temperature factor would also lead to difficulties. However, if three-dimensional data are used and an accuracy of better than 10 per cent in $F_{\text{obs.}}$ is attained, then the probability of the R value being low and yet the structure being wrong would be negligible.

Electroluminescence of Gallium Phosphide Crystals

In the first papers on the electroluminescence of gallium phosphide[1], photographs of the emission spectra of undoped and zinc-doped crystals were observed to differ. As a working hypothesis, Wolff, Hebert and Broder[1] suggested that zinc might form a luminescent centre in gallium phosphide analogous to copper in zinc sulphide. Carrying this analogy further, they proposed that the zinc centres are ionized by impact with charge carriers injected at the negative electrode (the luminescence in most cases originated at the negative electrode). Since this work was reported, several workers[2-5] have observed electroluminescence at grain boundaries in gallium phosphide polycrystals and have proposed p–n junction recombination to be the dominant luminescent mechanism. Grimmeiss and Koelmans[3] report that undoped or weakly zinc-doped electroluminescing polycrystals can be shown to contain both p- and n-type regions (they were mainly n-type) and all give the same emission spectrum. Heavily zinc-doped samples were uniformly p-type and did not electroluminesce. I have investigated the electroluminescence of gallium phosphide single crystals of uniform conductivity type and find the emission spectrum from undoped n-type crystals to be similar to that reported by Grimmeiss and Koelmans. Weakly zinc-doped crystals, however, are p-type (10^{17} carriers/c.c., 50 cm.^{2}/V. sec. mobility, from Hall effect measurements) and give a unique electroluminescence emission which is probably the same as that observed by Wolff *et al.* (The 'zinc' electroluminescence has also been observed by M. Gershenzon (private communication).) Heavily zinc-doped crystals are darker in colour and do not electroluminesce, in accord with the observations of Grimmeiss and Koelmans.

The crystals studied were grown from solutions of 10–20 atomic per cent of phosphorus in gallium by slow cooling from about 1,200° C. The silica vial was in a constant-temperature zone of the furnace throughout the crystal-growth operation. Zinc was introduced by mixing metallic zinc with the gallium and phosphorus before heating. The crystals obtained from these procedures are usually platelets with <111> faces and dimensions of about 5 × 2 × 0·5 mm. They are single crystals although in some cases X-ray diffraction data and etching experiments indicate 180° twinning. Single-crystal whiskers have also been obtained from sublimation of gallium phosphide crystals or powder and are also observed to electroluminesce. Undoped crystals are spectrographically pure except for traces of silicon. The effect of the silicon impurity on the luminescent properties is not yet known. (Some silicon-free samples have been prepared. Hence, it is not known whether silicon is actually present in the gallium phosphide lattice or is merely a surface contaminant.)

The electroluminescence emission spectra were obtained with a Bausch and Lomb grating monochromator and a 1P21 photomultiplier detector, the output of which was fed to a Moseley X–Y recorder. A potentiometer attached to the wave-length drive of the monochromator provided a linear wave-length scale on the X axis of the recorder. All spectra were corrected later on an equal energy basis for the spectral response of the detector. Silver paint electrodes were used for all the measurements reported here. They are rectifying with breakdown potentials of a few volts. In all cases the light emission originated at the negative electrode.

A typical electroluminescence emission spectrum of an undoped crystal is shown in Fig. 1. This resembles the spectrum reported by Grimmeiss and Koelmans except for the relative peak heights, which are markedly different. In their spectrum the height of the longer wave-length peak is roughly twice the height of the shorter wave-length peak. Their measurements, however, were made at low temperature, where internally excited photoluminescence could enhance the longer wave-length emission.

Emission spectra taken at room temperature and at about − 100° C. from a weakly zinc-doped crystal (approximately 0·001 per cent zinc) are shown in Fig. 2. The unique 'zinc' emission is clearly seen. Its peak at 7000 Å. is in contrast to the 5700 Å. and 6500 Å. peaks obtained from undoped crystals. It is more than an order of magnitude greater in energy than the 'undoped' emission which can be seen in Fig. 2 as a small peak near 6000 Å. The structure in the 'undoped' emission is masked by the overlap of the 7000 Å. band. The ordinates of the two spectra in Fig. 2 have been normalized to percentage of maximum brightness. The two spectra coincide,

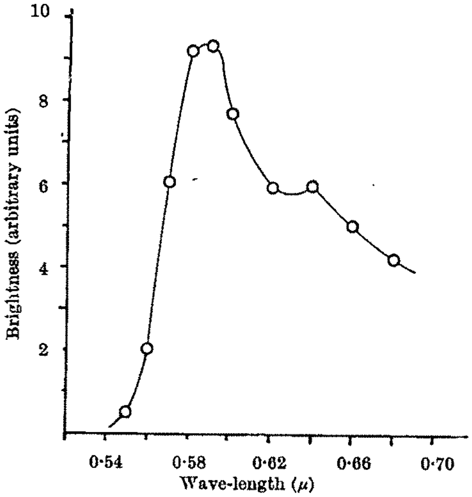

Fig. 1. Electroluminescence emission spectrum from undoped gallium phosphide crystal

approximately; the deviations have not yet been determined to be significant.

The results corroborate the observation of Wolff, Hebert and Broder, that a unique red electroluminescence is obtained from zinc-doped gallium phosphide. I have found, however, that the zinc concentration is critical; above about 0·01 per cent zinc only non-luminescent crystals are obtained. The lower limit on the zinc concentration is not known as yet. I am conducting experiments to correlate the amount of 'zinc' emission with the zinc concentration. It is possible that Grimmeiss and Koelmans did not observe the 7000 Å. emission because the concentration of zinc in their weakly doped crystals was too low, and in their heavily doped crystals too high.

The role of the zinc impurity in the luminescent process is not known. It is tempting to draw the analogy with copper in zinc sulphide. However, junction and impurity band formation have also been shown to play an important part in carrier injection electroluminescence[6], and it is conceivable that the zinc impurity is involved in this way.

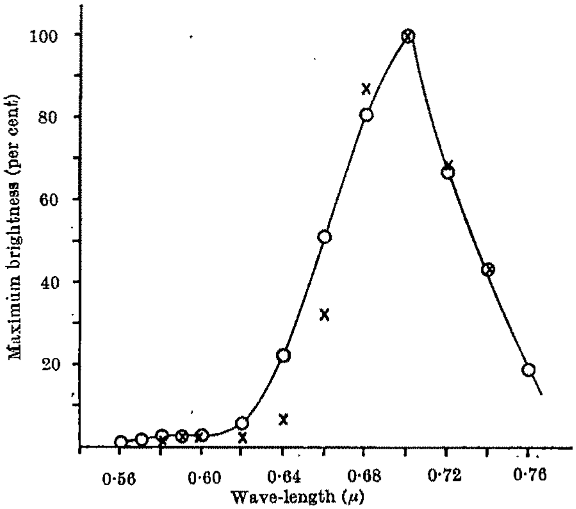

Fig. 2. Electroluminescence emission spectra from zinc-doped gallium phosphide crystal at room temperature and −100° C. (O, room temperature; ×, −100° C.

I wish to acknowledge the assistance of Messrs. E. L. Peirson and C. V. Osterday in the preparation of the crystals, and am particularly grateful to Prof. J. J. Dropkin for reading and commenting on this manuscript.

The Unit of Neutron Flux

WE wish to support the suggestion[1] that a unit of neutron flux be defined. We feel, however, that it would be more practical to define the chad as follows:

$$1 \text{ chad} = 10^{12} \text{ n./cm.}^2 \text{ sec.}$$

The flux in most existing or contemplated power reactors lies in the range of 10^{12}–10^{13} n./cm.^{2} sec., the flux in zero energy reactors is generally about 10^9 n./cm.^{2} sec., and that encountered in sub-critical assemblies is approximately 10^6 n./cm.^{2} sec. High-flux research reactors operate at flux-levels ranging up to about 10^{16} n./cm.^{2} sec. The whole range of applied neutron physics could therefore be covered conveniently by the chad, as defined above, and the associated units microchad (10^6 n./cm.^{2} sec.), millichad (10^9 n./cm.^{2} sec.) and kilochad.

While having no objection in principle to the definition suggested earlier (1 chad = 1 n./cm.^{2} sec.), we feel that our definition is more practical and convenient in that, in addition to eliminating the clumsy compound nomenclature, it will remove the necessity for inclusion of large powers of 10.

CRYSTALLOGRAPHY

Some Electron Microscopic Observations on Single Crystals of Polyethylene

SOME time ago it was found that in dilute solutions of polyethylene, particularly of 'Marlex 50', single crystals may be formed which can be made visible by means of electron microscopic techniques[1–3]. Morphologically, these crystals showed much resemblance to single crystals of paraffin, which were observed for the first time by Dawson and Vand[4]; the latter show a spiral terrace growth, the height of the terraces corresponding to the length of the chain molecules.

Keller[1] pointed out that the chains in the polyethylene crystal must necessarily be folded and that the height of the terraces corresponds to the distances between successive folds. He also noted that the crystals lose their crystallinity in the electron microscope, but that their morphological shape is probably preserved.

In an attempt to study undecomposed specimens, in which freshly prepared specimens were exposed

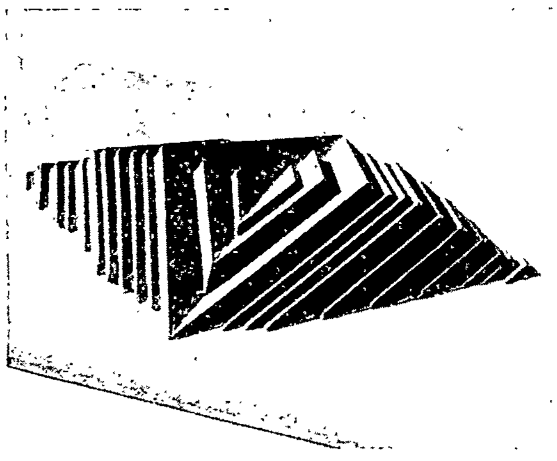

Fig. 1. Model of the striated structure of a polyethylene crystal

to a low-intensity electron beam, Keller and O'Connor[5,6] obtained completely different pictures. Although the crystal was still lozenge-shaped, it revealed a distinct division into four sectors, which were characterized by striations running non-parallel to the crystal boundaries, but which in our view were distinctly arranged in the (310) direction.

Some time ago we studied these types of crystals by electron microscopic stereo-techniques. From the micrographs we gained the impression that the crystals possess a pyramid-like structure. Using this technique, two micrographs are secured with the specimen set at different angles to the beam. As there was no visible difference between the two pictures, we concluded that the striations cannot possibly be due to extinction effects, as is sometimes stated in the literature.

Application of this technique requires that two pictures be taken of each crystal; owing to the change of the crystal in the electron beam, however, it is quite exceptional that two suitable micrographs will be obtained. To obviate this difficulty, we decided to use replica techniques. After some initial troubles had been overcome, we succeeded in securing pre-shadowed carbon replicas of polyethylene crystals.

We then took stereographs of these replicas; the first micrographs thus obtained completely confirmed our observation mentioned above with regard to the pyramidal structure. Some of the plates also revealed that the striations are straight. A model made of these structures is shown in Fig. 1. As can be seen from this model, the crystals do not have a true pyramidal structure, but can be better represented by a pyramid with a depressed apex. Mention ought to be made here of a statement by Bassett, Frank and Keller[7] that a pyramidal structure might be expected.

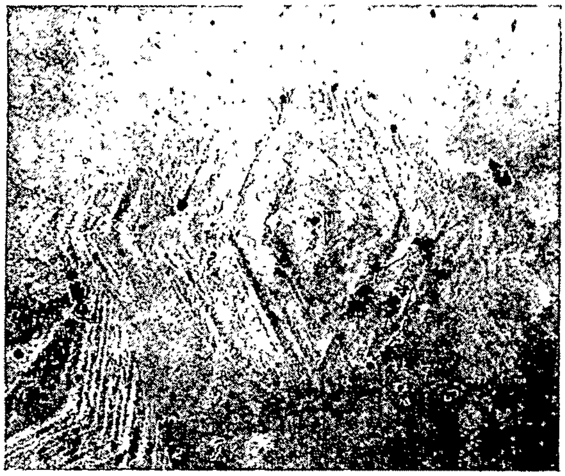

Fig. 2. Replica of a crystal of polyethylene. (× 15,000)

Although several attempts have been made in the past at explaining this striated structure, attention has never been directed to the relation between this structure and the spiral terraces observed in a later stage. In some of our replicas, both the pyramidal and the terraced structure can be seen (Fig. 2).

In view of the information provided by these micrographs, we expect that it will become possible to shed more light on the relation noted by us, and in general on the way in which polyethylene crystallizes from solution.

CHEMISTRY

Localization of Ferrous Corrosion by Azide

Among the very large number of rust inhibitors, one of the simplest in structure, sodium azide, has received only scant attention. I have made some observations on the interaction between ferrous materials and neutral aqueous solutions of azide at ambient temperature.

Mild steel normally remains immune under azide solution. In sufficient concentration, this additive counteracts the corrosive effect even of chloride[1]. However, if mild steel is submerged in 1 *M* sodium azide containing 0·2 *M* sodium chloride, a scratch is made on the metal with a glass needle, and an anodic potential applied (for example, 2 V. vs. a stainless steel rod as cathode), a sharp red line appears instantly along the scratch, as if the steel were bleeding. This demonstration of highly localized attack is, however, only successful if no more than a few minutes elapse between the 'wounding' and the application of potential. Otherwise the scratch immunizes itself, obviously by growing an oxide film under the galvanic action of dissolved oxygen. If the scratch is applied in air, healing by dry oxidation is less rapid, and the lesion may be developed by submersion and anodic treatment after much longer intervals of time. The red ferric azide complex issuing from the scratch later diffuses away and hydrolyses, leaving a cloud of ferric hydrate.

A high-carbon steel, several low-alloy steels, a variety of cast irons, and 13 per cent chromium iron behaved quite similarly. A ferritic 17 per cent chromium iron also gave a 'bleeding' effect, but in this case the electrolysis had to be applied not later than a few seconds after the steel had been scratched under the azide/chloride solution. Austenitic 18–8 type stainless steels gave no effect, even if they were made anodic while being scratched. The effect may therefore be developed as a sorting test for steels and perhaps also for showing corrodible areas in welds.

Voltage and concentrations are not critical for the effect to occur. Chloride may be replaced by bromide or iodide, but in the absence of halide the scratch does not develop. Attempts were made to replace azide by thiocyanate, which is iso-electronic with azide and also forms a red ferric complex. Thiocyanate, however, showed no localizing action. It is an anodic stimulator of corrosion, not an inhibitor.

The role of azide in these experiments is dual: as an inhibitor of the attack, and as a reagent of the product of attack. Similar effects can be produced with pairs of additives in which these two functions are separated; for example, with benzoate as inhibitor and ferroin as reagent. Also oxidation need not be electrolytic but can be galvanic, using oxidants such as persulphate. Ferricyanide can be used as oxidant and reagent in one, as in the 'ferroxyl test' for showing up pores in tin coatings of steel. Conspicuous localized corrosion should, then, be generally favoured by four factors: (*a*) oxidizing conditions, (*b*) the presence of a stimulator, (*c*) the presence of an inhibitor and (*d*) the presence of a reagent. Table 1 gives examples of such combinations by which corrosion limited to a scratch could be produced.

Table 1. SETS OF CONDITIONS LEADING TO SCRATCH ATTACK OF MILD STEEL

* Adjusted with sodium hydroxide to *p*H 7.

It is of interest to note that azide has none of the attributes normally held responsible for inhibition of rusting: in contrast to the structurally similar nitrite, and to chromate or picrate, it cannot act as an oxidant. It differs from the carboxylates in that it does not precipitate iron from solution, and from the amines by the absence of alkaline character. Unlike the proprietary rust preventives, it has a very simple structure. Further work on the azide/iron interaction may help to throw light on the still obscure mechanism of rust prevention by soluble additives.

I wish to thank the Mond Nickel Co., Ltd., for permission to publish this communication.

Hydrogen Bonding in Apatitic Calcium Phosphates

IT is well known that the formula of naturally occurring and of precipitated synthetic hydroxyapatite is $Ca_{10}(PO_4)_6(OH)_2$: the molar Ca/P ratio of these compounds is 1·667. The compound mentioned can adsorb a consistent amount of water. For other synthetic calcium phosphates, with lower Ca/P ratios, the X-ray diffraction spectrum remains the same.

By combining data principally obtained from infrared spectrometry, X-ray diffraction and chemical methods of investigation, we have established that the general formula of the apatitic calcium phosphate series is: $Ca_{10-x}(H)_x(PO_4)_6(OH)_{2-x}$, the value of x varying from 0 to 2. Detailed results concerning this problem have been presented in a preliminary report with some restrictions appropriate to such an over-simplified view[1]. According to our conception, some $PO_4^{\equiv}$ groups of these compounds are in fact $HPO_4^{=}$ groups which are linked by hydrogen bonds: (O_3PO—H- - -OPO_3). In our work, special attention has been paid to hydrated tricalcium phosphate (Ca/P ratio = 1·5), or $Ca_9(O_3PO$—H- - -$OPO_3)(PO_4)_4(OH)$.

Others have reported similar findings in this field[2-4]: they point out that pyrophosphate, derived from these acidic groups by heating below 600° C., may be determined by chemical means and are also present in bone and teeth.

A paper published recently[5] gives us the opportunity to present some complementary information. According to these authors, infra-red spectra obtained from apatitic calcium phosphates with a Ca/P ratio between 1·667 and 1·5 show a band located at 3,400 cm.$^{-1}$ which is attributed to the O—H valence vibration of the (O_3PO—H- - -OPO_3) groups. The intensity of this absorption increases when the Ca/P ratio of the compounds considered decreases: apparently, this observation agrees with the conception of Posner *et al.*[5], the amount of $HPO_4^{=}$ groups being inversely proportional to the Ca/P ratio. However, it does not agree with the findings of other workers[6-8], who have shown that this vibration absorbs at about 2,850 and 2,400 cm.$^{-1}$. Moreover, when the frequency 3,400 cm.$^{-1}$ is plotted on the graph obtained by Lord and Merrifield[8], the distance O—O corresponds to 2·85 Å.; on the other hand, the distance observed for acidic phosphates is only 2·5 Å.[9,10], and this value agrees with the location of an absorption band at 2,400 cm.$^{-1}$. In our records, obtained with apatitic calcium phosphates with a Ca/P ratio lower than that of hydroxyapatite, we have actually observed a weak band located at 2,400 cm.$^{-1}$ and another one, with a high intensity, at 3,400 cm.$^{-1}$. The latter is also present on the spectrum of synthetic hydroxyapatite and consequently is not specific to the compounds with a Ca/P ratio lower than 1·667: as is well known, it corresponds to adsorbed water.

Probably, Posner *et al.*[5] have compared synthetic apatitic phosphates to natural hydroxyapatite, which does not contain adsorbed water and shows no band at 3,400 cm.$^{-1}$ as it has been verified by us. The inverse proportionality observed by them between the Ca/P ratio and the intensity of the 3,400 cm.$^{-1}$ wave may be explained as follows: the lower the Ca/P ratio of the synthetic calcium phosphates, the smaller are the crystals and the greater is the total surface of these crystals: in this way, the amount of adsorbed water is greater, as can be shown experimentally. Like Posner *et al.*[5], we have observed on the infra-red spectra obtained with natural hydroxyapatite a band (3,560 cm.$^{-1}$) corresponding to the vibration of free OH groups. The same band appears when larger crystals of hydrated tricalcium phosphate, obtained by treating in the hydrothermal bomb, are studied: in this way, the amount of adsorbed water is much smaller than in the untreated compound, and the band corresponding to free OH groups clearly appears.

Calcium Exchange of Bone Salts considered as a Measure of the Crystal Surface

COMPARING the *in vitro* calcium-45 uptake by bone salts (ashed by a method slightly modified from that of Gabriel) from alcoholic and aqueous calcium-45 labelled calcium chloride solutions, we have been able to demonstrate the occurrence of remodelling phenomena (chemical reaction between the solid and the ions dispersed in the liquid phase, recrystallization *sensu stricto*) and of an isoionic exchange, which reaches an equilibrium when 8 per cent of the calcium ions of the solid are involved. All remodelling processes being discarded, we believe that this figure corresponds to a pure exchange value. In our conditions, the intracrystalline ion exchange by thermal vibration is too slow to interfere with the surface exchange process[1].

In a recent paper[2] Engström, correlating X-ray diffraction data and electron microscopy investigations, states that the needle-like crystal of bone salt has an average diameter of about 50 Å. This figure is also given by Molnar[3].

If the needle-like crystal is considered as a cylinder of the same length, the base surfaces not being taken into account, one may calculate, as a percentage, the ratio—plane volume of the surface/volume of the crystal—in the following way:

$$\frac{\pi h(2Rd - d^2)}{\pi R^2 h} \times 100 \text{ (per cent)}$$

where h is the length of the crystal; R is the radius of the crystal base; d is the third dimension of the surface plane volume. After simplifying, it becomes:

$$\frac{2Rd - d^2}{R^2} \times 100 \text{ (per cent)}$$

which in the particular case of bone crystals gives:

$$\frac{4{,}900}{625} = 7\cdot85 \text{ per cent}$$

when d is equal to the unit (1 Å.).

It is interesting to point out that the length of the crystal is of no importance for this calculation. This calculated figure corresponds closely to the experimental exchange value in such a way that the latter may be considered a real measure of the crystal surface. This assumption implies that the composition of the surface is not different from the composition of the bulk of the crystal. If the ratio is expressed in m.^{2}/gm. we obtain a value 250 m.^{2}/gm., which also fits the published figures[4].

Lifetime of the Pyrene Dimer

THE appearance of a new fluorescence emission band in concentrated solutions of pyrene was attributed by Förster and Kasper[1] to an excited dimer formed by combination of an excited singlet molecule with an unexcited molecule. Stevens and Hutton[2] have recently reported the lifetime of the dimer emission to be $1\cdot8 \times 10^{-3}$ sec. During tests of a new photoelectric spectrophosphorimeter an attempt was made to record this long-lived emission. The instrument was a modification of a spectrofluorimeter previously described[3], but in which two 800 c./s. choppers were used, one being situated in the beam of the exciting light and one in the beam of the fluorescence light. The choppers were driven by synchronous motors, and by rotation of one of the motors the choppers could be put into or out of phase so that the fluorescence monochromator could be made to record either the sum of the fluorescence and phosphorescence spectra or the phosphorescence spectrum alone. By adjustment of the photomultiplier voltage and by variation of the amplifier gain, the overall sensitivity could be increased by a factor of 10^4.

The operation of the instrument was checked by measurement of the visible phosphorescence from a 0·005 per cent solution of eosin in anhydrous glycerol which was reported by Mlle. Boudin[4] to have a lifetime of about 10^{-3} sec. We found the ratio of the intensities of fluorescence and phosphorescence to be, within a factor of two, the same as the value reported by Mlle. Boudin.

The efficiency of the choppers was tested by measurements on aerated solutions of fluorescein and anthracene, and it was found that the recorded intensity of the fluorescence was reduced by a factor of more than 10^5 when the choppers were moved to the out-of-phase position.

A 10^{-3} *M* solution of Light's pure pyrene in B.D.H. spectroscopically pure cyclohexane was thoroughly de-aerated and sealed in a silica optical cell. The total luminescence spectrum was first measured using two different wave-lengths for excitation, namely, 366 mμ with viewing at right angles to the beam of exciting light, and 313 mμ with viewing in the same direction as the beam of exciting light. The spectrum was the same in each case and was similar to that reported by Forster and Kasper, and by Stevens and Hutton. The measurements were then repeated, but with the choppers out of phase and with the sensitivity increased by a factor of 10^4. The apparent phosphorescence emission from the dimer, measured in this way, had an intensity less than 10^{-5} times that of the total luminescence from the dimer. It was thus estimated that a component of the dimer emission having the lifetime reported by Stevens and Hutton must have an intensity less than 10^{-5} times the total dimer emission and that the greater part of the dimer emission must have a lifetime less than 5×10^{-5} sec.

The measurements with our spectrophosphorimeter set an upper limit to the lifetime of the pyrene dimer. A lower limit can be determined by measurement of the oxygen-quenching of its luminescence. Saturation of the 10^{-3} *M* solution with air was found to reduce the intensity of the monomer luminescence by a factor of about 7 and that of the dimer luminescence by a factor of approximately 19. In a 10^{-5} *M* solution, where dimer formation can be neglected, saturation with air reduced the intensity of the monomer luminescence by a factor of about 22. Assuming that the dimer is formed by combination of an excited singlet molecule with a normal molecule, and that oxygen quenching of both the monomer and dimer is collisional, it can be shown that:

$$F_D{}^0 \Big/ F_D = F_M{}^0 \Big/ F_M \, (1 + k_d \, \tau_d[\mathrm{O}_2])$$

where F_D is the intensity of dimer luminescence in 10^{-3} *M* solution containing oxygen, $F_D{}^0$ is the corresponding value in the absence of oxygen, F_M and $F_M{}^0$ are the corresponding intensities of monomer luminescence in the same solution, k_d is the bimolecular oxygen quenching constant for the dimer and τ_d the lifetime of the dimer in the absence of oxygen. The encounter frequency in *cyclo*hexane at 20° C. (that is, the maximum possible value for k_d) is $6 \cdot 8 \times 10^9$ litre mole^{-1} sec.$^{-1}$, and the oxygen concentration in an air-saturated solution is $2 \cdot 5 \times 10^{-3}$ *M* (ref. 5). Hence $\tau_d \geqslant 10^{-7}$ sec. The corresponding values for the monomer lifetime are $\tau_M \geqslant 3 \cdot 5 \times 10^{-7}$ sec. in 10^{-3} *M* solution and $\tau_M \geqslant 1 \cdot 2 \times 10^{-6}$ sec. in 10^{-5} *M* solution. The latter value is in approximate agreement with the value of $0 \cdot 5$–$1 \cdot 0 \times 10^{-6}$ sec. which we estimated from the intensity of the long wave-length absorption band system.

The evidence from our experiments gives a value for the lifetime of the dimer which is at least thirty times less than that found by Stevens and Hutton, a discrepancy for which it is difficult to find an explanation. One possibility which we considered was that the long-lived emission was due to solute or photochemical decomposition products, adsorbed on the wall of the vessel (it being assumed that any luminescence from the vessel wall would have been included in the total phosphorescence spectrum measured by Stevens and Hutton). However, no evidence of a 'wall-adsorption' effect was found in our experiments with 10^{-3} *M* pyrene solution in the silica cell, the ratio of 'phosphorescence' to fluorescence being the same, within experimental error, whether right-angle illumination (366 mμ) or frontal illumination (313 mμ) was used (in the latter arrangement the illuminated cell face, and hence also the luminescence from any adsorbed matter, was viewed by the photomultiplier). Whatever the cause of the discrepancy it is sufficiently important to merit further investigation.

[3] Parker, C. A., *Nature*, **182**, 1002 (1958).
[4] Boudin, S., *J. Chim. Phys.*, **27**, 285 (1930).
[5] Munck, A. U., and Scott, J. F., *Nature*, **177**, 587 (1956).

WE previously reported[1] a value of $1 \cdot 8 \times 10^{-3}$ sec. for the lifetime of the pyrene dimer in de-aerated *cyclo*hexane solutions. This value was obtained from the exponential decay of the emission observed from a flashed solution, the order of magnitude being confirmed by photographing the emission excited by a constant intensity source through a Becquerel phosphoroscope in which the time interval between excitation and observation was $\sim 5 \times 10^{-4}$ sec. Although it was not actually stated, it was implied that this lifetime referred to the total dimer emission.

In an attempt to repeat this observation Parker and Hatchard (preceding communication) report that they were unable to record an emission component of this duration for a similar solution and conclude that if such a component is present it must have an intensity less than one part in 10^5 of the total dimer emission which has the much shorter lifetime of 5×10^{-5}–10^{-7} sec.

We have again measured the lifetime of the long-lived component by recording the pyrene emission from the phosphoroscope on a Mazda 27*M*3 photomultiplier tube and photographing its signal on a Solartron oscilloscope type *CD* 711*S*.2; the apparatus was tested by measuring the emission lifetime of uranyl sulphate crystals for which the observed value of $2 \cdot 53 \pm 0 \cdot 03 \times 10^{-4}$ sec. is in excellent agreement with the published[2] lifetime of $2 \cdot 55 \times 10^{-4}$ sec. For a 10^{-3} *M* solution of pyrene a component of lifetime $1 \cdot 75 \pm 0 \cdot 1 \times 10^{-3}$ sec. was observed which confirms the value previously obtained.

In order to measure the ratio of slow to fast components of the dimer emission, the apparatus was modified as described by Williams[3] and the intensity of the slow component was found to be 0·2 per cent of the total dimer emission. Clearly our previous implication that the two different emission spectra observed from pyrene solutions are respectively associated with slow and fast emission components was unjustified and the system of electronic states must be more complex than we at first visualized.

At lower temperatures (− 10° C.) in liquid paraffin we have observed a value of 60×10^{-3} sec. for the long-lived pyrene component; this could be ascribed to the suppression of an energy-dependent first-order radiationless decay of the dimer which should lead to overall self-quenching of fluorescence in pyrene solutions at room temperature. It is possible, however, that the residual oxygen in the outgassed solutions partially quenches the long-lived component at room temperature but is much less effective in the more viscous paraffin at − 10° C. The radiative lifetime of the slow component may therefore exceed 60×10^{-3} sec. and in the complete absence of oxygen this component may contribute appreciably to the total intensity of dimer emission.

The problems associated with the outgassing of solutions are not simplified by the observation that the pressure in a vessel sealed-off at 10^{-7} mm. may be increased to as much as 10^{-2} mm. by the act of sealing-off (Heavens, O. S., private communication); since quartz requires a higher seal-off temperature it is possible that the failure of Parker and Hatchard to observe the slow component is due to a comparatively high pressure of gas released from their quartz vessels during seal-off.

BIOCHEMISTRY

Origin of Urinary Pyrocatechol

The formation of pyrocatechol in rats fed shikimic and quinic acids has recently been reported by Booth *et al.*[1] They proposed that human urinary pyrocatechol might have a similar origin since these acids are present in some edible plants. However, pyrocatechol also could arise from the oxidation of phenol, a compound formed in the gut by the action of bacteria on protein[2]. If pyrocatechol excretion-rates were shown to be dependent on gut bacteria, support for the proposed relationship would be obtained. An examination was therefore made of the pyrocatechol excretion-rates in several normal persons who later were treated with large doses of neomycin, a drug which can virtually sterilize the gut.

Pyrocatechol was determined fluorometrically by an adaptation of the method of Weil-Malherbe and Bone[3]. An aliquot of the urine, adjusted to *p*H 1 with hydrochloric acid, was heated to 100° C. for 10 min. and then made neutral by the addition of dilute base. An alumina adsorbate was prepared, and an aliquot allowed to react with the ethylenediamine reagent. The neutral fluorescent derivative which formed was extracted into *iso*butanol and its fluorescence compared with that of pyrocatechol using a Farrand photofluorometer. The specificity of the method for urinary pyrocatechol was determined by paper chromatography of the concentrated *iso*butanol extract. Under ultra-violet illumination only one major fluorescent spot was seen which had the same R_F and blue-green colour as similarly prepared pyrocatechol or norepinephrine. It has been shown that identical ethylenediamine derivatives are formed from both pyrocatechol and norepinephrine[4]. Since only trace amounts exist in urine no correction need be made for the norepinephrine.

While pyrocatechol excretion-rates in the normal person exhibit a large diurnal variation, daily excretion-rates remain rather constant[5]. When neomycin is ingested in large doses, however, the daily excretion-rates of pyrocatechol decline rapidly as shown in a typical result listed in Table 1. From these results a major fraction of urinary pyrocatechol appears to be dependent upon the activity of gut bacteria. Since phenol can be converted to pyrocatechol by the animal organism[6], the formation of the major urinary catechol may proceed as follows:

Table 1. Pyrocatechol Excretion-Rates before and during the Administration of Neomycin in a Daily Oral Dose of 8 gm.

Pre-treatment period		During neomycin treatment	
Days	Pyrocatechol excretion (mgm./day)	Days	Pyrocatechol excretion (mgm./day)
1	6·0	4	3·2
2	5·2	5	1·2
3	5·8	6	1·6

$$\text{tyrosine} \longrightarrow \text{phenol} \longrightarrow \text{pyrocatechol}$$

Although the conversion of tyrosine to phenol appears to be mediated by an enzyme present in coliform bacilli[7], further oxidation may be non-enzymatic. The site of this oxidation could be within the gut since pyrocatechol has been reported present in fæces[2], but oxidation of unconjugated phenol by other body organs probably can occur.

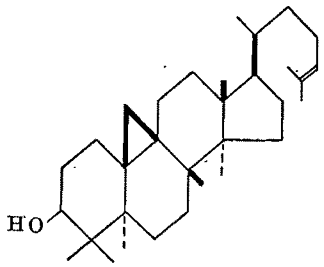
Cyclo-Arthenol : a Minor Constituent of Linseed Oil

Cyclo-Arthenol has been isolated by Barton[1] in addition to the corresponding ketone, *cyclo*-arthenone, from the latex of the *Artocarpus integrifolia* fruit and afterwards by Spring and co-workers from the unsaponifiable part of *Strychnos nux vomica*[2,3]. These authors have studied its structure and have demonstrated that *cyclo*-arthenol may be correctly described as 9 : 19-*cyclo*lanost-24-en-3β-ole :



Other compounds of similar nature are *cyclo*-laudenol[4], *cyclo*-eucalenol[5] and 24-methylen*cyclo*-artanol[6], all of which are characterized by the presence of a *cyclo*-propane ring at 9–19.

In the course of work on the constituents of the unsaponifiable fraction of vegetable oils I have

Table 1

	Alcohol, $C_{30}H_{50}O$, from linseed oil		Data quoted by:									
			Barton (ref. 1)		Spring (refs. 2, 3)		Gonzales (ref. 10)		Chapon (ref. 11)		Shimizu (ref. 6)	
	m.p.	$[\alpha]_D$	m.p.	$[\alpha]_D$	m.p.	$[\alpha]_D$	m.p.	$[\alpha]_D$	m.p.	$[\alpha]_D$	m.p.	$[\alpha]_D$
Alcohol	115–116	+51·4	85–92	+48	115	+54	97–112	+47	80–105	+48·5	114–115	+52
Acetate	121–122	+60·2	122·5 123·5	+58	122–124	+59·5	118·2	+54	119–120	+58	122–124	+59
Benzoate	129–130	+68	129–130	+65	130	+76	129	+54	130	+67	129–130	+75

isolated, by chromatography of the neutral[7] unsaponifiable of a linseed oil of Italian production on silicic acid, a group of materials characterized by a yellow-brown Liebermann–Burchard reaction. Paper chromatography[8] shows the presence in this fraction of three different substances at least, probably terpenic alcohols. Subsequent chromatography of the fraction on aluminium oxide made it possible to isolate, by elution with hexane–benzol, a substance which after crystallization from methanol melted at 115–116° C., $[\alpha]_D = +51 \cdot 4°$. This substance gave a yellow-brown colour with the Liebermann reagent and a distinct yellow colour with nitromethane; paper chromatography showed the presence of only one component.

The compound isolated has been characterized through the acetate and the benzoate; in Table 1 are recorded the values of specific rotations and of the melting points, which agree satisfactorily with those obtained for the *cyclo*-arthenol by the authors mentioned.

Identification has been confirmed through the infra-red spectrum of the compound isolated from linseed oil, which was identical with that reported by Cole[9] for the *cyclo*-arthenol. Finally, the mixed melting point of the acetate of the compound, with a sample of genuine acetyl-*cyclo*-arthenol, kindly supplied by Dr. Spring, did not show any decrease of melting point.

This investigation suggests that triterpenic alcohols of the same group may be present in other animal and vegetable oils, such as olive oil, maize germ oil, peanut oil and tallow oil.

A Bilatriene Pigment in the Green Terebellid Polychæte *Eupolymnia heterobranchia* (Johnson)

Eupolymnia heterobranchia (Johnson) is a relatively large terebellid found in mud and under boulders on the Pacific coast of North America. All the specimens that I have found near Friday Harbor, Washington, had a deep green colour. This is due to granules of green pigment deposited in the cœlomic cells and in the epidermis. The pigment was readily extracted with acidified methanol, gave a good Gmelin reaction, and reacted positively to the zinc bilipurpurin test, demonstrating that it was a bilatriene. The red-fluorescent compound obtained in the latter test had a sharp maximum at 625 mμ (Unicam), indicating the presence of meso- rather than proto- side chains[1]. The great resistance of the pigment to concentrated sulphuric acid also distinguished it from biliverdin. In a 5 per cent hydrochloric acid : methanol mixture the absorption spectrum showed peaks at 360 and 675 mμ, resembling mesobiliverdin hydrochloride (363 and 670 mμ; ref. 1).

Mesobiliverdin has been found to occur in only a few animals, and these are all phytophagous insects[2]. The occurrence of a similar pigment in *Eupolymnia* is interesting in view of the report by Berkeley and Berkeley[3] that orange-red individuals are sometimes found. It would be most interesting to know whether the appearance of these orange worms is due merely to a lack of the green pigment or, as is just possible, to mesobilirubin or related pigment.

Occurrence of *Cyclo*-Propene Acids in Some Plants of the Order Malvales

STERCULIC and malvalic acids are the only fatty acids known to contain a *cyclo*-propene ring in their structures. From the seed oil of *Sterculia foetida* (Sterculiaceae), Nunn[1] isolated sterculic acid (C_{19}) and defined its structure. Malvalic acid (C_{18}) isolated from Malvaceae by Shenstone and Vickery[2] has been structurally identified by Macfarlane, Shenstone and Vickery[3] and Craven and Jeffrey[4]. Afterwards we reported[5] the occurrence of minor amounts of sterculic acid associated with malvalic acid in the oils from some malvaceous plants. The occurrence of both acids in the seeds of *Sterculia foetida* and two species of Malvaceae has also been observed by C. R. Smith, jun., T. L. Wilson and K. L. Mikolajczak (private communication).

We have measured the concentrations of malvalic and sterculic acids in the seed and leaf oils of three species from each of the families, Malvaceae and Sterculiaceae. The solvent-extracted oils were saponified under mild conditions, and the total fatty acids were subjected to low-temperature crystallization. The filtrate contained almost all the *cyclo*-propene acids, and saturated acids were absent. Malvalic and sterculic acids were cleanly separated by the method of reversed-phase column chromatography[6]. They were closely preceded by, and sometimes merged with, linoleic and oleic acids, respectively.

The Halphen colour test, given by both *cyclo*-propene acids[3] but not by other unsaturated acids, was used to estimate the concentrations of malvalic and sterculic acids in the isolated chromatograph 'peaks'. The colour reaction given by each fraction was adjusted in a series of increasing dilutions to a point near visual extinction. The colours were then compared with a similar series obtained from standard concentrations of pure acids. The ratio of dilutions at similar colour intensities gave the concentration of *cyclo*-propene acid present in each impure fraction.

In the seed-oil of *Sterculia foetida* the colorimetric method was checked by an estimation of the products of partial hydrogenation of the fatty acids. In the hydrogenation, ethanol was used as a solvent with 5 per cent palladium on calcium carbonate as a catalyst. The *cyclo*-propane acids, dihydromalvalic and dihydrosterculic acids, together with small amounts of their methyl-branched derivatives, were separated from the straight-chain saturated acids by crystallization and afterwards isolated after reversed-phase and gas-liquid chromatography. The concentrations of the *cyclo*-propene acids estimated by the colorimetric and hydrogenation methods agreed within ± 2 per cent.

Malvalic and sterculic acids in the chromatographic fractions were identified after direct isolation by means of fractional crystallization. In some samples, however, identification was effected more readily by conversion of the *cyclo*-propene acids to the stable dihydromalvalic and dihydrosterculic acids.

Table 1. CONCENTRATIONS OF MALVALIC AND STERCULIC ACIDS IN PLANT OILS*

Plant family and species	Source of oil	Malvalic acid (per cent)	Sterculic acid (per cent)
Malvaceae			
Malva parviflora†	leaves	6·9–13·9	3·1–6·1
Malva verticillata‡	leaves	1·5–3·7	0·3–0·8
Gossypium hirsutum	seeds	0·7–1·5	0·3–0·5
Sterculiaceae			
Brachychiton acerifolium	leaves	nil	nil
	seeds	6·1–8·1	1·4–1·9
Brachychiton populneum	leaves	nil	nil
	seeds	8·9	1·1
Sterculia foetida	seeds	4·4	45·6

* When expressed as percentages of the total fatty acids, these values will be increased by factors of 1·14–1·25 for the seed oils and 1·49–1·82 for the leaf oils.

† Total *cyclo*-propene acids in seed oil = 5·0 per cent.

‡ Total *cyclo*-propene acids in seed oil = 1–2 per cent.

The concentrations of malvalic and sterculic acids in the oils from several plant species are given in Table 1. In the oils containing *cyclo*-propene acids both occur together, and the concentration of malvalic acid exceeds that of sterculic acid in five of the six species examined. The seed oil of *Sterculia foetida* is exceptional in its high concentration of *cyclo*-propene acids and in the preponderance of sterculic acid. In oils where malvalic acid predominates, the highest concentrations of *cyclo*-propene acids occur in *Malva parviflora* (up to 20 per cent of the oil or 35 per cent of the total acids) and in *Hibiscus syriacus* (25 per cent of the total acids). The concentrations in freshly extracted, unrefined oils of cotton seeds (*Gossypium hirsutum*) were always low but in most samples fairly constant, while in *Malva* spp. the concentrations in the leaf oils were very variable. There is evidence from the chromatograms of the presence of other *cyclo*-propene acids, but so far it has been impossible to isolate sufficient amounts for identification.

We are indebted to Mr. K. E. Murray for isolation of the *cyclo*-propane acids by gas-liquid chromatography.

Identification of Œstradiol-17_β Testosterone and its Precursors from *Scylliorhinus stellaris* Testes

SINCE its first isolation by Laqueur *et al.*[1] in 1935 from tissue of steer testis, testosterone has been obtained from some species of mammals only, namely, horse and man, by Ruzicka *et al.*[2,3]. Furthermore, Brady[4], by *in vitro* experiments on the biosynthesis of testosterone from ^{14}C-acetate, indicated that testosterone is probably the androgenic testicular hormone in two additional species, rabbit and hog. Androgenic substances of non-mammalian vertebrates are still unknown. On the other hand, œstradiol-17_β has been found to be the œstrogenic hormone not only in mammals but also in the elasmobranch *Squalus suckleyi*[5], in the lungfish *Protopterus annectens*[6], in birds[7] and in the starfish *Pisaster ochraceus*[8]. The investigation of the androgenic material in non-mammalian vertebrates seems therefore necessary to fill this gap, and is of obvious evolutionary importance.

We have started an investigation of the androgenic steroids by their direct determination in the testicular tissue of the elasmobranch *Scylliorhinus stellaris*. 110 gm. of material were obtained from six sexually mature animals and extracted according to the method of Ruzicka *et al.*[9]. The acetonic residue was refluxed with chloroform in order to eliminate urea, which is present in large amounts in elasmobranch tissue. The steroid fraction was separated by counter-current distribution. The neutral fraction (25 mgm.) was then resolved by paper chromatography in systems developed by Bush[10]. The phenolic fraction (81 mgm.) was chromatographed according to the system developed by Heftmann[11].

Neutral fraction. First chromatography in system 'Bush *C*' showed the presence at the starting line of blue tetrazolium-positive material, which probably corresponds to corticosteroids. Five spots were identified in successive paper chromatographies by short-wave ultra-violet light and rechromatographed. Three of these spots corresponded to testosterone, androstenedione and progesterone on the basis of the constant R_F values and absorption maxima. The spots corresponding to androstenedione and progesterone showed the characteristic colour blue-violet and blue, respectively, with the Zimmermann reaction. The spot corresponding to testosterone, after elution and oxidation with CrO_3, was rechromatographed in system Bush *A*. The oxidation product showed the same R_F as androstenedione.

According to semiquantitative estimation these steroids were present in the amounts of approximately

50 μgm./kgm. of testosterone, 70 μgm./kgm. of androstenedione and 100 μgm./kgm. of progesterone.

The two additional unidentified spots both showed absorption maxima at 240 mμ and the positive Zimmermann reaction. One of these gave an R_F value of 0·50 in system Bush B_3 (25 ± 1° C.); the other one gave an R_F value of 0·79 in system Bush A (25 ± 1° C.).

Phenolic fraction. The phenolic fraction resolved by paper chromatography and the ferric chloride plus $K_3[Fe(CN)_6]$ colour reaction showed the presence of œstradiol-17_β amounting to about 20 μgm./kgm.

The present investigation has demonstrated that the androgenic substances secreted by the testis of the elasmobranch *Scylliorhinus stellaris* are the same as those of mammals. Furthermore, as in mammals, œstradiol-17_β is present as well[3,12,13].

Especially interesting is the identification of progesterone, which has not been isolated before from testis tissue, but has been considered as a probable precursor of testosterone. In fact Slaunwhite and Samuels[14] demonstrated, by *in vitro* work, the biosynthesis of 17_α-hydroxyprogesterone, androstenedione and testosterone from isotopically labelled progesterone.

This investigation was supported by a research grant *RG*-6455 from the Division of General Medical Sciences, U.S. Public Health Service.

Occurrence of Catecholamines in Acrania and Invertebrates

The occurrence of catecholamines in vertebrates has been extensively studied in recent years after the development of simple and accurate methods for the quantitative assay of such compounds. Relatively few investigations have been carried out with regard to their presence in invertebrates, however.

Biedl[1] and Gaskell[2] concluded from biological assay of extracts of leeches and the earthworm that these contained adrenaline. Later Erspamer and Boretti[3] showed the presence of *p*-hydroxyphenylethanolamine (octopamine) in the posterior salivary glands of *Octopus vulgaris*. These glands were also found to contain noradrenaline[4].

In an extensive investigation Östlund[5] found 0·13 μgm. of adrenaline and 0·48 μgm. of noradrenaline/gm. in the ventral ganglionic chain of *Lumbricus terrestris*, thus confirming the presence of catecholamines in this annelid. Similar amounts were found in *Arenicola marina* (lugworm). In a variety of other invertebrates Östlund[5] found only traces of catecholamines, however (less than 0·01 μgm./gm.). In insects, on the other hand, he observed relatively large amounts of adrenaline, noradrenaline and dopamine.

In the present experiments various invertebrates were collected fresh and extracted with 3–5 volumes of 10 per cent trichloroacetic acid. The catecholamines were adsorbed on an alumina column and eluted with acetic acid. Adrenaline and noradrenaline were estimated by a fluorimetric technique according to Euler and Lishajko[6].

The results are presented in Table 1. It will be seen that adrenaline and noradrenaline could not be demonstrated with certainty in invertebrates except in the annelid *Lumbricus terrestris* and in the larvæ of *Pieris brassicae*, the common cabbage white butterfly. This is in agreement with the previous findings of Östlund[5], who found in larvæ from various insects from 0·01 μgm. to 0·075 μgm. of adrenaline and from 0·1 to 1·3 μgm. noradrenaline per gm. In the present work the adrenaline content in the *Pieris* larvæ was negligible, while the noradrenaline content was 0·33 μgm./gm. From these results it is obvious that noradrenaline not only occurs in remarkably high amounts in insects' larvæ but also that it occurs greatly in excess of adrenaline.

Table 1. Adrenaline and Noradrenaline in Invertebrates and Acrania (Whole Animals, in Mesothuria Visceral Organs)

Phylum	Species	Adrenaline (μgm./gm.)	Noradrenaline (μgm./gm.)	Total weight (gm.)
Aschelminthes	*Priapulus caudatus*	< 0·005	< 0·005	15
Mollusca	*Buccinum undatum*	< 0·005	< 0·005	23
	Mytilus edulis	< 0·005	< 0·005	250
Annelida	*Lumbricus terrestris*	0·003	0·015	80
	Eumenia crassa	< 0·005	< 0·005	125
Crustacea	*Carcinus maenas*	< 0·005	< 0·005	44
Insecta	*Pieris brassicae* (larvæ)	< 0·005	0·33	47
Echinodermata	*Mesothuria intestinalis*	< 0·005	< 0·005	20
Urochordata	*Ciona intestinalis*	< 0·003	< 0·005	30
Acrania	*Branchiostoma lanceolatus**	< 0·005	0·16	5·6

* Syn. *Amphioxus.*

The presence of definite quantities of noradrenaline in *Branchiostoma*, 0·16 μgm./gm. in the whole animal, is of some interest since it indicates that this primitive organism is capable of synthesizing noradrenaline. On the other hand, there was no evidence of adrenaline.

The results presented have thus confirmed, by fluorimetric technique, the presence of considerable amounts of noradrenaline in *Lumbricus terrestris*, larvæ of *Pieris* and in *Branchiostoma lanceolatus*. Adrenaline was also found, as previously noted[5], in small amounts in *Lumbricus*. In the other invertebrates studied, the amounts of adrenaline and noradrenaline, if present at all, were extremely small.

Effects of Speciation on Serum Proteins in the Genus *Macaca* with Special Reference to the Polymorphic State of Transferrin

The effects of speciation on the serum proteins of macaque monkeys and other primates are being studied in our laboratory by a combination of starch-gel electrophoretic and immunological techniques[1,2]. In an initial survey of the sera from 19 cynomolgus monkeys (*Macaca irus*) and 17 rhesus monkeys (*Macaca mulatta*) we found that the cynomolgus sera contained a larger proportion of γ-globulin than the rhesus sera and also that all the cynomolgus sera showed only one transferrin whereas 10 of the 17 rhesus sera showed more than one transferrin. At the time, we observed that one of the ten rhesus sera showed three transferrin components and that in the other nine sera, each of which showed two components, the relative positions of the transferrins in starch-gel varied in some cases between the samples. In order further to define the polymorphic state of transferrin in the species *Macaca mulatta* and the apparent absence of this state in the species *Macaca irus*, the sera from 40 more rhesus monkeys, newly arrived from India, and from 40 more cynomolgus monkeys, newly arrived from the Philippines, were kindly provided for study by Parke, Davis and Co. The rhesus monkeys in this shipment were captured in an area the size of a township near the Nepal border. It was not possible to trace exactly where in the Philippines the cynomolgus monkeys were captured. We have now detected fourteen transferrin patterns in the rhesus monkeys and still only one pattern in the cynomolgus monkeys. Thirteen of the transferrin patterns were represented in the last shipment. Our work, then, not only independently confirms but also considerably extends the report by Blumberg[3] of eight transferrin patterns in rhesus monkeys. Our results are particularly interesting in indicating that while the environment of one species selects for a polymorphic state, the environment of a closely related species selects against this state.

Although two-dimensional starch-gel electrophoresis[4] in a discontinuous buffer system[5,6] followed by immunological examination of the separated, fast migrating β proteins clearly demonstrated whether one, two or three transferrin components were present in a serum sample, comparative one-dimensional starch-gel electrophoresis revealed the subtler differences in the mobilities of the transferrins. Fig. 1*A* presents a typical result gathered by this latter type of screening in which a number of sera are run side by side in a large gel. Note the uniformity of the transferrin band in the 5 cynomolgus sera in contrast to the variability of the transferrin bands in the five rhesus sera. The fourteen transferrin patterns, of which type I is identical with the cynomolgus transferrin band, are shown in Fig. 1*B*. The actual homology of the cynomolgus and rhesus transferrins to human transferrin was established by two-dimensional starch-gel immunoelectrophoresis[6]. Fig. 2 presents the results of an immunoelectrophoretic experiment in which we employed one of our unispecific, chicken antisera[7] to human transferrin.

The transferrin types represented in Fig. 1 can be subdivided into those showing one component, types I, II, III and IV ; type V showing two components which almost merge ; those showing two closely adjacent components, types VI, VII and VIII ; those showing two components increasingly separated from each other, types IX and X, then types XI and XII, and finally type XIII; and the last showing three components, type XIV. Fig. 1 also lists the distribution of sera among these types. In this connexion the breakdown of sera among types I, II and V is still being checked, for a number of repeated determinations are needed to differentiate a large single band of transferrin from two which touch each other.

The genetics of the rhesus transferrins has still to be investigated. Yet by analogy to the human transferrins[8] we postulate that certain of these types (particularly those in the first sub-division) are con-

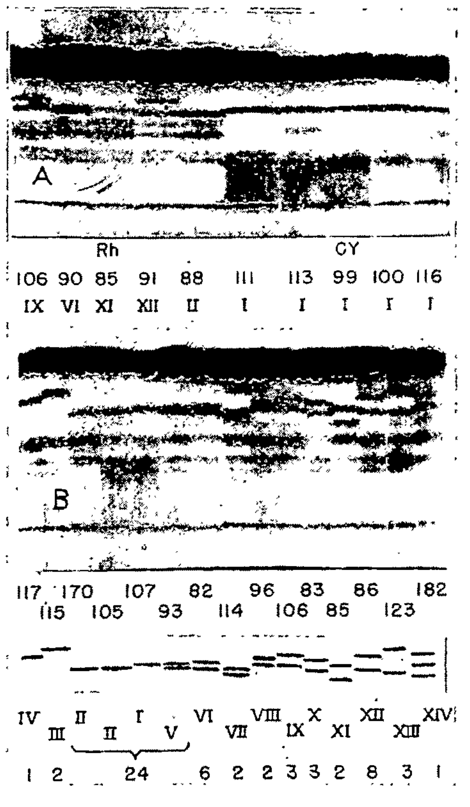

Fig. 1. *A*, Comparative one-dimensional starch-gel electrophoresis of five rhesus and five cynomolgus sera. The sample designations and the transferrin types of these samples are printed below the photograph of the gel. *B*, Comparative one-dimensional starch-gel electrophoresis of 15 rhesus sera representing the 14 transferrin types. Below the photograph of the gel and the sample designations, that portion of the photograph showing just the transferrin bands is presented diagrammatically. The numerical breakdown of the rhesus sera among the various transferrin types is presented below

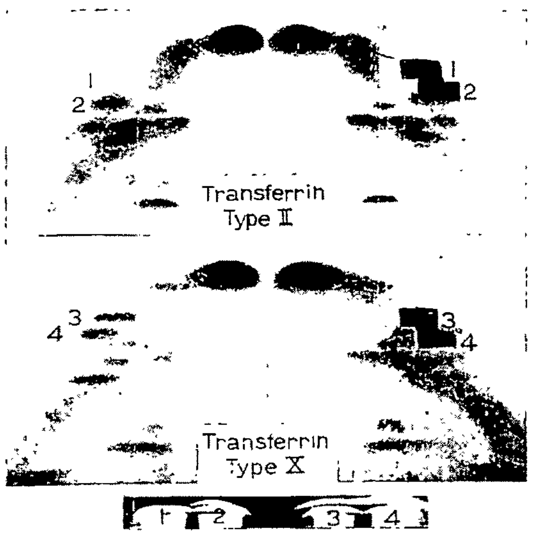

Fig. 2. Two-dimensional starch-gel immunoelectrophoretic identification of transferrin in type II and type X rhesus sera. One-half of each gel was first stained with amido black to show the distribution of protein components (photographs on the left). Then from the unstained halves pieces of gel, estimated to contain the transferrin or to serve as a control, are cut out. Then these halves are stained (photographs on the right). The pieces of gel are placed at the bottom of an immunoelectrophoretic chamber, overlaid first with agar, then with unispecific antiserum to human transferrin. After 12 days incubation the reactions were photographed (photograph on the bottom). Positive precipitin lines, demonstrating the presence of transferrin, were afforded by gel pieces 2, 3 and 4 but not by 1, the control piece. The lateral non-specific band which always forms just above the starch-gel may be discounted

trolled by homozygous combinations of genes and the other types by heterozygous combinations of genes. Although it would be necessary to test further specimens and other species of macaques to relate the frequencies of transferrins to the taxonomy of the genus, nevertheless it is clear that there are sharp species differences in the degree of polymorphism of transferrin.

In another approach to the detection of species differences in the state of the proteins, we found that our unispecific immune reagents could be used to measure as well as identify protein components in the macaque sera. For example, the relative γ-globulin concentration of each cynomolgus and rhesus sera was determined by immunochemical assay with a uni-specific anti-human γ-globulin reagent[9]. By this convenient means we clearly show that we are measuring the monkey protein equivalent to human γ-globulin. Though there is some overlapping of high rhesus and low cynomolgus values, the cynomolgus sera have a much larger mean γ-globulin concentration than the rhesus sera, 17·2 per cent as compared to 10·7 per cent. The difference in the means by the *t* test is significant at the 0·1 per cent level of confidence.

A more detailed account of the application of our experimental procedures to the study of primate proteins will be prepared later. It should be emphasized at this point, however, that the equivalent proteins in man and monkey are antigenically related, but not identical.

We wish to thank Dr. Paul E. Ayers of the Parkedale Unit, Parke, Davis and Co., for his generous cooperation in providing the sera and for the information relative to the geographical location of the monkeys. This research was supported by grant 226 of the National Multiple Sclerosis Society, grant *M*–2476 of the National Institute of Mental Health, and grant *G*–14152 of the National Science Foundation.

PHYSIOLOGY

Polypnœa evoked by heating the Scrotum of the Ram

THERMAL or electrical stimulation of discrete regions in the brain of several species can cause specific and vigorous thermo-regulatory responses[1-3]. It is equally clear that in sheep and calves, the polypnœa in response to raised environmental temperatures may start before the temperature of the blood supply to the brain changes[4,5]. It was concluded that in these ruminants the thermal stimulus to panting can be entirely peripheral in origin. Whether the receptors concerned were concentrated in special areas of skin or were uniformly distributed over the surface of the body remained unresolved.

During experiments designed to examine the thermo-regulatory properties of the Merino ram's scrotum, a reflex polypnœa was observed to be initiated and sustained when this region was specifically heated. In 12 experiments on 5 rams, this was examined by enclosing the closely clipped scrotum in an insulated chamber through which dried air was circulated continuously. Temperatures were recorded at least once every minute from thermo-couples in the air outflow from the chamber, in the rectum at a depth of 10 cm., and in some experiments on the mid-posterior surface of the scrotum. The air of the room was controlled at 17 ± 2° C. throughout all experiments. Records were obtained for 1 hr. with the ram standing quietly and with air at 23 ± 4° C. passing over the scrotum. Scrotal air temperature was then rapidly raised to either 45 ± 1° C. (in 9 experiments) or 40 ± 1° C. (in 3) for 1–1½ hr. A typical response is shown in Fig. 1.

The mean respiratory-rates during the control periods ranged from 34 to 66/min.; in most experiments the respirations were quiet and almost imperceptible. The respirations became more definite and their frequency increased while scrotal air temperature was rising. The mean respiratory-rates varied from 61 to 171/min. in the first 30 min. of heating, they increased to 114–185/min. during the next 30 min. and were 117–163/min. in the final 30 min. Maximum respiratory rates of more than 200/min. were recorded during 3 experiments involving 3 of the rams. The typical response was not open-mouthed

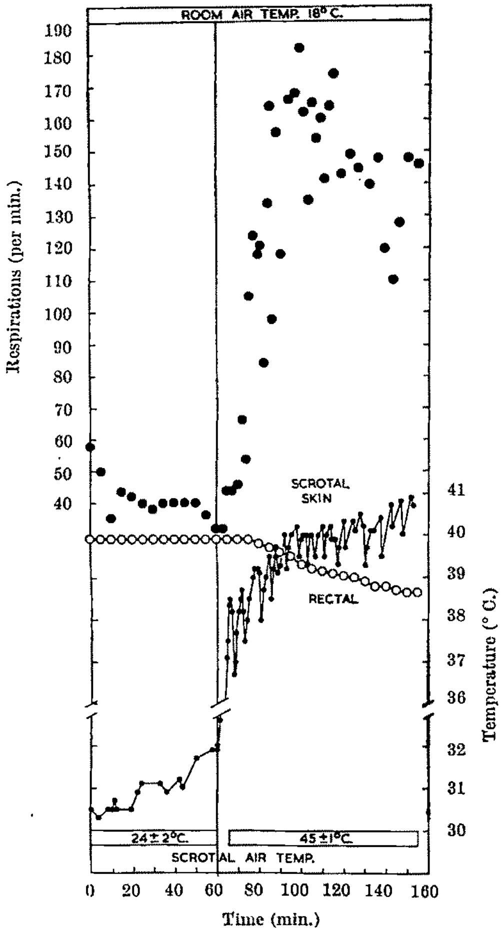

Fig. 1. The changes of respiratory-rate (●), rectal temperature (O–O) and scrotal skin temperature (●–●) induced by heating the scrotum of a ram with air at 45° C.

The falls of skin temperature occurring during the heating coincide with mass discharges from the sweat glands of the scrotum (Waites, unpublished observations)

panting, but a rapid polypnœa associated with a moist muzzle.

To confirm that the scrotal skin of each ram was specially sensitive to temperature, an area of mid-side skin equal to the area of the scrotum was close-clipped and heated with air at 45 ± 1° C. The respiratory response was negligible: mean frequencies were 45–65/min. during the control period, and 43–71/min. during the heating. It must therefore be concluded that the skin of the scrotum of the ram is particularly well endowed with peripheral thermal receptors.

No change in rectal temperature was detected before the start of the polypnœa, but thereafter rectal temperatures fell by 0·3–1·25 deg. C. in all experiments. In 7 of the 12 experiments, rectal temperature dropped at the rate of 0·5–1·0 deg. C./hr. and in these the fall started sharply within 8–18 min. after the onset of the polypnœa (Fig. 1). If the thermal inertia of the rectum of the ram is the same as that of the calf[6], then changes in rectal temperature would lag behind changes in blood temperature by 5–10 min. This would mean that in these experiments the temperature of the blood supplying the brain starts to fall almost immediately after the onset of the polypnœa. Furthermore, the polypnœa was sustained in spite of the continued rapid fall in deep-body temperature, a response which is paradoxical since the air ambient to the rest of the body was cool.

Thus, these results support the view that a thermally induced polypnœa can be evoked in rams without a previous rise in central temperature. Moreover, they show that the fall in deep-body temperature which followed the increase in respiratory-rate did not extinguish the reflex while the scrotal skin was being heated. The nature of the receptors and their pathways have yet to be described. However, it is now apparent that in the ram the scrotal cutaneous receptors alone are capable of influencing general body temperature, giving a broader thermo-regulatory role to the scrotum than the purely local one previously considered[7,8].

Polypnœa evoked by heating the Udder of the Goat

At the suggestion of Dr. Waites (preceding communication), we have similarly tested the udder of the female goat, because the sensory innervation of the udder and the scrotum are essentially the same[1].

In seven tests on 2 non-lactating pregnant Saanen goats, the immersion of the udder in a stream of air at 45° C. caused a rise in respiratory frequency from 20–40/min. to 100–120/min. after a latency of 5–60 min. Neither passing air at udder-skin temperature over the udder nor heating an equivalent area of the abdomen in front of the udder had such an effect. In two tests on a third dry, non-pregnant goat with one mammary gland transplanted on to the neck[2], the heating of this denervated gland was without effect on respiration, but when the control gland in the normal position was heated, the onset of panting occurred after 20 min. Although the rectal temperature tended to rise during the periods in the laboratory, the onset of polypnœa could not be related to this rise, which occurred equally in control experiments.

These preliminary observations confirm the finding of Waites that the inguinal region appears to be more sensitive to temperature than the general body surface of ruminants.

Recovery of Fertility after Protracted Steroid-induced Sterility in Mice

PROGESTERONE is known to prevent luteinization in experiments with guinea pigs[1]. The anti-luteinizing property of synthetic 19-norprogesterone and halogenated progesterone derivatives as absorbed from subcutaneously implanted pellets is greatly superior to that of natural progesterone[2,3]. The anti-luteinizing effect of these compounds can be made evident in experiments both with œstrogen-induced luteinization in ovarian grafts[4] and with spontaneous luteinization in the ovary *in situ* (guinea pigs[5], mice and rats). The anti-luteinizing effect of progestational compounds is not due to a direct action on the ovary but to a mechanism in which most probably the hypophysis and the hypothalamus are involved[6,7]. The physiological interest of these phenomena lies in the fact that the quantities absorbed per day from a subcutaneous pellet of progesterone and sufficient to antagonize luteinization are apparently not greater than those produced by the normal ovary *in situ*[4,8]. However, the findings are also of clinical interest; the progestational compound is also anti-ovulatory[9], in such a way that the anti-luteinizing action is implicitly also an anti-ovulatory one. Ample use of the anti-ovulatory action of progestational compounds has been made by Pincus *et al.* in experimental[10] and clinical[11] work.

The question arose whether the anti-ovulatory and anti-luteinizing faculty of progestational compounds can be made use of for the purpose of inducing protracted sterility and whether fertility can be recovered after a steroid-induced protracted sterility.

Mice, the life-cycle of which is such a short one and the reproductive activity of which deteriorates several months before death[12], are most suitable for such investigations. Our experiments were made with the strain *Balb-A* in use in this laboratory for several years; reproductive activity in this strain begins at the early age of two months, and is, under routine laboratory conditions, a stable one. But it starts to deteriorate 11–12 months later. Pellets of the highly active 19-norprogesterone were implanted subcutaneously; the pellets contained 20–40 per cent of this compound mixed with 80 and 60 per cent of cholesterol respectively.

20 per cent pellets were implanted into 10 mice 65 days old. The animals were killed 15 days later. Absorption was at the rate of 4–9 μgm. a day (for calculation of absorption from pellets containing a mixture of the specific steroid with cholesterol, see ref. 13). Corpora lutea were absent in 9 of these animals; the corpus luteum in the remaining animal was in a state of degeneration. In a group of 9 normal females 79 days old corpora lutea were present in 7 animals.

20 per cent pellets were implanted into 7 females 51–54 days old; 40 per cent pellets were implanted into another group of 7 females 40–51 days old. The experimental animals were maintained for the following 108 days with males in the same cage. None of these 14 animals became pregnant though they had reached the age of 5 months. In another group of 8 females 40 per cent pellets were implanted. The animals have now been sterile for 176 days and have reached the age of more than 7 months; that their sterility is not due to a failure of the male companion is shown by the fact that 2 other animals of the same group which lost implanted pellets had in the course of the same time 6 litters.

Table 1

No.	Age at implant. of pellets (days)	19-nor-progest. per day (μgm.)	First litter after removal of sterilizing pellets (days)	Size of first litter after removal of pellets
		20 per cent pellets		
5102	51	2	30	8
5094	54	2	30	11
97	51	2·6	no litter†	—
92	54	4·4	45	7
96	51	4·4	32	2
91	54	?*	31	10
93	54	?*	18(?)	9
		40 per cent pellets		
5103	51	12	37	8
12	42	12	22	13
07	49	13	35	9
13	42	13	42	9
21	40	13	22	8
11	42	15	22	7
04	51	16	36	4

14 females *Balb-A* aged 40 to 54 days, implanted subcutaneously with two pellets of 19-norprogesterone. Pellets were removed 108 days later, when the animals were 5 months old. Males were present in the same cage from the beginning of steroid treatment. No pregnancy occurred before removal of pellets.

* Only 1 pellet found 108 days after implantation.

† *Added in proof.* First delivery 86 days after removal of pellets. Size of first litter, 5; subsequent deliveries of 11, 5 and 7.

Pellets were removed after having remained in the above 14 animals for 108 days. Absorption was at the rate of 2–4 μgm. a day with 20 per cent pellets, and of 12–16 μgm. with 40 per cent pellets. The animals were left with the same male as before. As seen from Table 1, 13 out of 14 animals became pregnant at 1–24 days after the removal of the pellets. The average number of young in the litter was 8, that is, no less than in the first litter of normal females of this strain which is of 6·7 (average of 15 normal animals). In one case (No. 5112) the size of the first litter after protracted sterility was even larger, reaching the maximum as observed in our normal animals.

In other words, after protracted steroid-induced sterility, full recovery of fertility occurred. The young were suckled as with normal litters; this was the case even with twelve young out of a litter of thirteen (No. 5112). The animals belonging to these litters began their reproductive activity at the normal age of about two months.

As mentioned above, the reproductive activity of females in *Balb-A* begins deteriorating at about the age of 13–14 months. It may be assumed that an experimentally induced sterility of three months in *Balb-A* mice corresponds to no less than five years in women.

Added in proof. The experiment in which 8 females with 19-norprogesterone remained sterile during 176 days has now also been concluded. All the animals remaining with the same male as during the sterility period became pregnant after the removal of the pellets and produced litters 20–42 days later. The average size of the litters was 6·25, 6·25 and 5·9 at the first, second and third delivery; that is, these females behaved as regards fertility like normal females. Six months of the reproductive life-span in our mice are assumed to be equivalent to not less than ten years in women.

We acknowledge financial help from the Population Council, New York, given to one of us (R. I.). Thanks are due to Dr. A. Zaffaroni, director of Syntex, Mexico, for a gift of 19-norprogesterone.

Arginine and 'Neurosecretory' Material in the Pituitary Gland of the Pig

IN a previous publication[1], the distribution of arginine as demonstrated histochemically by an improved Sakaguchi reaction[2] was examined in sections of rat pituitary gland. The results were discussed in relation to present knowledge of the origin and chemical nature of the hormones of the pituitary gland, with particular reference to the correlation between the stainable 'neurosecretory' material of the pars nervosa and the octapeptide antidiuretic-vasopressor hormone (ADH-vasopressin). It was further suggested that a similar examination of the neurohypophysis of the pig would be of interest since the ADH-vasopressin extracted from the posterior lobe of the pituitary of this animal contains lysine in place of arginine. Unfortunately, there does not appear to be a specific histochemical method for lysine; nevertheless, some information may be derived by applying the reaction for arginine, for if the stainable 'neurosecretory' material represents the hormones oxytocin and ADH-vasopressin, as postulated by the neurosecretory theory, then it might be expected to give no reaction for arginine in the case of the pig.

This communication describes results of such a preliminary investigation; pituitary glands were fixed in Susa or Lewitsky's fluid and the methods used were as described previously[1].

By comparison of adjacent sections it was found that the 'neurosecretory' material of the pars nervosa of the pig, as stained by the chrome alum-hæmatoxylin method, showed no reaction for arginine. However, other structures within the same section, such as cells of the pars intermedia, acidophils of the pars anterior, blood vessels and connective tissue fibres, gave a positive reaction for arginine, as did also 'neurosecretory' material in sections of rat pituitary stained under exactly the same conditions and used as a 'control'. It is therefore concluded that arginine is either very low in concentration or absent from 'neurosecretory' material in the pars nervosa of the pig, as predicted from the known chemical structure of pig ADH-vasopressin and the theory of neurosecretion. The investigation is being extended to other species.

I wish to thank Dr. F. R. Johnson, of the Department of Anatomy, for his help and advice on the photomicrography, and Mr. L. G. Cooper, of Messrs. T. Wall and Sons, Ltd., London, N.W.10, for providing the pig pituitaries, which were obtained within 30 min. of death.

Renal Proliferation in the Unilaterally Nephrectomized Rat

RENAL growth following unilateral nephrectomy has been referred to as 'compensatory renal hypertrophy'[1]. The work of Rollason emphasizes the importance of hyperplasia in this process[2]. Utilizing thymidine as a specific precursor of deoxyribonucleic acid (DNA), and assuming the constancy of DNA in the absence of dividing cells, the incorporation of thymidine serves as an index of cellular proliferation[3]. We now describe the effect of uninephrectomy on the incorporation of tritium-labelled thymidine into renal DNA.

Male Wistar rats, approximately 4 weeks of age and weighing 40 gm., were housed in colony cages and maintained on 'Purina Laboratory Chow' and water *ad lib.* Experimental and control groups were chosen at random from a group of sixty rats. Left nephrectomies and sham operations were performed under pentobarbital sodium anæsthesia (29 mgm./kgm. body-weight intraperitoneally). 36 hr. following the operative procedure each animal received intraperitoneally three separate injections, 1 hr. apart, of tritium-labelled thymidine, 20 μc./kgm. body-weight: 24 hr. following the last injection, the animals were killed by decapitation, the kidneys removed and frozen. DNA protein was isolated from the kidneys according to a modification of the Schmidt–Tannhauser procedure as outlined by Friedkin[4]. The dried DNA protein was weighed into a counting vial and 1 ml. of methanolic 'Hyamine' (Packard Instrument Co., Chicago, Illinois) was added. The vials were sealed and heated in a water-bath at 55° C. for 18 hr.; 5 ml. of a toluene scintillation solvent system were added[5]. A homogeneous solution was obtained by swirling. The vials were cooled to 4° C. and counted in a liquid scintillation counter (Packard Instrument Co.). The final counts were corrected for quenching by use of an internal standard. In order to express the counts as counts per min. per milligram of DNA, an aliquot of each DNA protein sample was heated with 3 per cent perchloric acid for 15 min. at 70° C., and the optical density of the supernatant solutions was read at 265 and 295 mμ and compared

Table 1

	No. of Animals	Average weight of total renal tissue (mgm.)	Per cent restoration of renal tissue	Thymidine incorporation (c.p.m. per mgm. DNA)	*P*
Nephrectomy	8	634	45	970 ± 84*	< 0·0001
Sham	4	877		488 ± 31*	

*Replicate determinations upon pooled tissue.

to a DNA standard (Sperm DNA, California Biochemical Co.).

A representative experiment is shown in Table 1. The unilaterally nephrectomized animals incorporated 100 per cent more labelled thymidine than did the control, sham-operated rats. These results, obtained with tracer amounts of tritium-labelled thymidine, are, according to our present concepts, indicative of increased cellular proliferation in the remaining kidney of the unilaterally nephrectomized rat[6]. They support the morphological work previously cited and recent reports concerning DNA synthesis in the uni-nephrectomized rat utilizing other techniques[7,8].

The mechanism(s) regulating such growth is poorly understood; however, Ogawa and Nowinski have reported a specific renal mitosis-stimulating substance in the serum of uni-nephrectomized rats[9]. We have found that kidney slices in a balanced salt–glucose medium incorporate tritiated thymidine into DNA at a measurable rate. Work is being carried out utilizing this *in vitro* technique as an assay for the presence of growth-promoting factors in the serum of unilaterally nephrectomized animals.

The Distribution of Light in an Image formed in the Cat's Eye

Flamant[1] has estimated the distribution of light in the image formed in the human eye of a brightly illuminated slit. By the kindness of Prof. Arnulf and Mlle. Flamant of the Institut d'Optique in Paris, we were allowed to use their apparatus and method to make similar measurements on the eyes of cats. Visual stimuli have been used for electrophysiological work on the visual system of the cat, and it is often important to know how accurate an image is formed.

The cat was anæsthetized with 'Nembutal'; the pupil was dilated and the accommodation fixed with atropine. The image of a narrow slit of light formed in the cat's eye was photographed by the method described by Flamant[1] for the human eye. The eye was placed in Maxwellian view, so that a small image of the source was formed near the centre of the pupil, and an image of the slit at the tapetum. The light reflected from the tapetum was observed after emerging through the pupil, and the correcting lens was adjusted to make the tapetal image, as observed, as sharp as possible.

The principle of the method is to measure the increase in width of the photographic image of the retinal image of a vertical slit the intensity of which varied from top to bottom. It was immediately obvious that the image was much less sharp than that formed in the human eye. Satisfactory photographs were obtained from one cat only, but two others were examined and appeared to have images of similar size. When the image could be formed on the tapetum the reflexion was very much greater than that from the human eye, so that much shorter exposures were required.

The light which was photographed had traversed the eye media twice, once entering through a small central area of the pupil, and once leaving, after dispersion by the tapetum, through the whole of the dilated pupil. It is assumed that scattering in the second transit is equivalent to that occurring when the eye forms an image with the pupil dilated, and that scattering in the first transit is negligible in comparison. Fig. 1 thus represents the distribution of light in the retinal image of a point source when the light enters the eye through the whole of the dilated pupil. At 12 min. of arc from the centre of the image the intensity has fallen to about 50 per cent of its original value, at 32 min. the intensity is down to about 10 per cent. The spread of the image is about 6–8 times greater in these experiments than in those on the human eye. The conditions of our measurements were, however, different: the eye was atropinized and the position of the image on the cat's retina was not known—it was not necessarily very close to the central area. Comparison with human

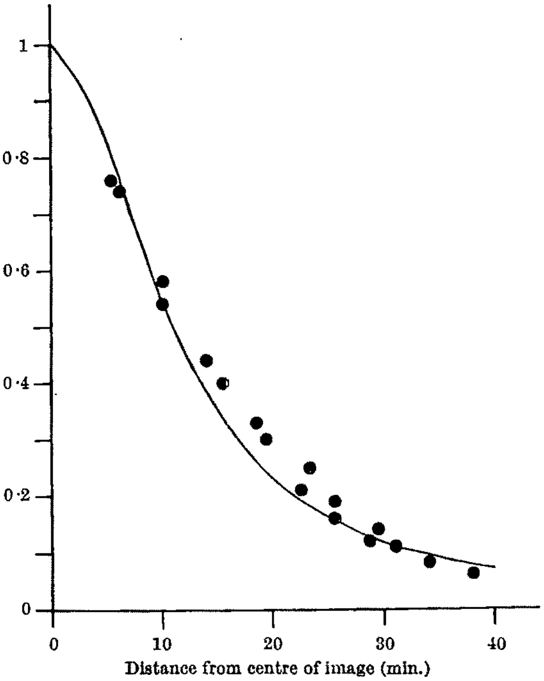

Fig. 1. Relative intensities at different angular distances from the centre of the image of a point source of light viewed by a cat's eye with pupil dilated

results may therefore be misleading. The experiments show that the images of small light sources formed by the cat's eye may be very blurred when light enters through the whole of the dilated pupil. They give no information about the scattering which takes place when light enters only through a small area in the centre of the pupil; this is likely to be much less.

We are grateful to Prof. Arnulf and Mlle. Flamant for allowing us to use their apparatus and for their assistance with the experiments. This work was supported by research grant *B*–1810 from the National Institute of Neurological Diseases and Blindness, United States Public Health Service, and both authors received Medical Research Council personal grants.

A Neuronal Model for Conditioning

THE difficulty of explaining conditioning in terms of a simple neuronal model has been discussed by Burns[1]. The problem lies in the fact that the only relatively long-lasting type of facilitation that has so far been experimentally demonstrated involves presynaptic terminals so that activity of neurones in the unconditioned reflex pathway cannot be expected to facilitate synaptic connexions from neurones which converge on to them from another afferent pathway. Eccles has proposed a rather complex neuronal model to avoid this difficulty[2]. Even this is admitted to be inadequate since it requires that the conditioned and unconditioned stimuli be applied simultaneously, and even then could only provide a low-level bombardment of the synapses which must be facilitated unless additional reverberating circuits are included. There is evidence to suggest that reverberating circuits do play a part in the early stages of conditioning[3,4], but no complete model including them has been proposed.

The following simple scheme appears to fulfil many of the requirements: the neurones of the unconditioned reflex pathway are linked to the afferent neurones excited by the conditioning stimulus through a number of parallel reverberating circuits. Each unit (Fig. 1) is reciprocally linked through synapses with similar parallel units. The synaptic resistance must be such that impulses from *C.S.* alone result in the damped oscillation of only a few of the units. If impulses from *U.S.* impinge on the circuits while damped oscillations initiated by *C.S.* are still present, then spatial facilitation occurs and additional parallel circuits are recruited. Once a critical number of parallel units is activated the oscillations become self-maintaining because of reciprocal reinforcement. When the oscillations eventually die down the synapses linking *C.S.* to *E* through *A*, *B* and *C* remain facilitated.

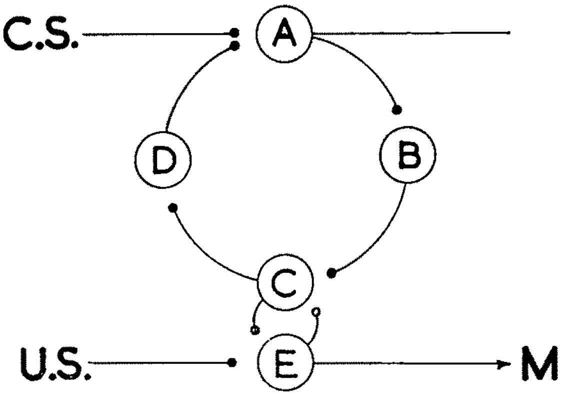

Fig. 1. *A*, *B*, *C*, *D* and *E* represent nerve cell bodies in a model unit. *C.S.* is the afferent pathway for conditioned stimuli and *U.S.* for the unconditioned stimulus. *M* represents the motor pathway for the unconditioned response

A difficulty arises. *E* is continuously bombarded with impulses during the initial stage of the conditioning process which may be expected to prolong the reflex greatly. It seems possible that activity in *E* may be cut off by negative feedback once the reflex has been fulfilled.

I thank Dr. B. D. Burns for his comments.

Local Endotoxin Hypersensitivity and its Relation to the Shwartzman Phenomenon

ALTHOUGH there have been previous claims that lesions like the Shwartzman phenomenon can be produced by two large injections of endotoxin into the same site in the skin, in animals other than rabbits (for example, mice)[1], it has been stated that the classical Shwartzman phenomenon is immunologically non-specific in that it does not depend on antigen–antibody reaction[2,3], and it can be elicited only in rabbits[2–4]. Recently, however, I have succeeded in demonstrating that the first phase of the Shwartzman phenomenon, that is, preparation of the skin by endotoxin, is a specific reaction depending on a well-characterizable immunological mechanism, namely, the phenomenon of local endotoxin hypersensitivity, and that in appropriate circumstances (*a*–*e*) it may be elicited by endotoxins on the skin of guinea pigs and rats also.

These characteristics are:

(*a*) Guinea pigs and rats, 3–4 weeks previously sensitized with *S. typhosa* or *E. coli*, will produce hæmorrhagic skin lesions at sites prepared with 25–50 μgm. endotoxin, on intravenous injection of 50–100 μgm. endotoxin 24-hr. later. (The sensitization was carried out by the weekly subcutaneous injection of 0·5–1, 0–1, 0–2 × 10^{-9} bacilli. Typhoid and *coli* endotoxin prepared by the Boivin method were reprecipitated three times by a double volume of ethanol. Their Shwartzman-reactive unit was 3 μgm.) Animals not pretreated with the bacteria do not produce hæmorrhagic lesions. These experiments proved that the endotoxin must not be derived from the same bacterial species as was used for sensitization.

(*b*) 0·025–0·1 ml. rabbit antiserum, obtained by hyperimmunization with typhoid endotoxin, injected into the skin of guinea pigs or rats, followed after 24 hr. by intravenous endotoxin, results in skin hæmorrhage.

(*c*) Mixture of typhoid endotoxin (25–50 μgm.) with colloidal silver (50–100 μgm.) for intracutaneous injection and subsequent intravenous challenge (0·1–1·0 μgm. endotoxin and 10–20 mgm. colloidal silver) results in skin hæmorrhage in guinea pigs at 6–8 hr.

(*d*) Normal rabbit mononuclear peritoneal exudate cells (2–10 × 10^4) obtained 4 days after paraffin oil had been introduced in the peritoneal cavity[5], injected intracutaneously in guinea pigs, and followed by 50–100 μgm. endotoxin intravenously after 24 hr., result in skin hæmorrhage.

(*e*) Normal guinea pig or rat mononuclear peritoneal exudate cells (5–10 × 10^4) injected intracutaneously in guinea pigs or rabbits, and followed by 100 μgm. endotoxin intravenously after 24 hr., result in skin hæmorrhage.

The histology of the skin lesions (6–8 hr. after intravenous challenge) resembled that of the Shwartzman phenomenon in rabbits.

a–c could be explained by localization of endotoxin in relatively high concentrations in the skin by the antibody or by the effects of colloidal silver. Antibody which combines with endotoxin has been shown (in some instances at least) not to neutralize its toxic properties. A specific additional effect of antigen–antibody reaction or of colloidal silver might or might not be involved, but it does not seem proved.

d and *e* can scarcely be explained in the same way, since the peritoneal exudate cells do not produce secreted antibody in normal circumstances. The possibility is worth examining that they carry delayed type hypersensitivity to endotoxin, and that the combined result of a delayed type reaction and intravenous endotoxin is a Shwartzman phenomenon.

I wish to thank Dr. E. Kelemen for advice and generous help throughout this work.

Lactic Acid Concentration in the Kidney of the Golden Hamster, *Mesocricetus auratus*, in Different Conditions of Diuresis

WORK by Zerahn on frog skin[1] and by Leaf on the bladder of the toad[2] have produced evidence that the active transport of sodium is accompanied by a proportional consumption of oxygen; glycolysis and lactic acid production also increase, according to Leaf, with the active transport of sodium in aerobic conditions.

It is known that the renal emunctory is also a site of intense transfer of sodium through the convoluted and collector tubes from the urine to the plasma; in addition, it seems that consumption of oxygen is related to such a process[3]. In the present communication we present the results obtained on lactic acid concentration in the cortex and papilla of the kidney in three different experimental conditions: (1) after 12 hr. fasting: (2) under water diuresis (samples of renal tissue taken 1½ hr. after the administration of distilled water to the amount of 5 per cent of the animal's weight by gastric tube); (3) under mannitol diuresis (samples of renal tissue taken 1½ hr. from the subcutaneous administration of 7·5 ml. per cent bodyweight of a 10 per cent mannitol solution).

Mesocricetus auratus was selected for experiments as the renal cortex of its kidney can be easily separated from the papillary tissue (Fig. 1). The lactic acid has been measured by Barker and Summerson's method[4] using as a standard lithium lactate purified according to Schatzkes[5]. Each examination was made on samples of approximately 40 mgm. of papilla tissue and 100 mgm. of cortical tissue, frozen in liquid nitrogen as soon as they were taken from the animal; the two samples of cortex and papilla which were compared came from the same kidneys.

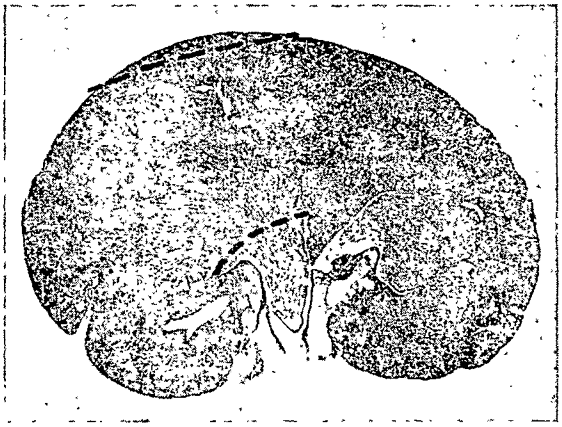

Fig. 1

The results are shown in Table 1. From these a constant and significant difference of the lactic acid content in the papilla and in the cortex appears in all conditions. If one excludes a state of relative hypoxia in the papillary zone, this difference could account for greater chemical work in the papilla than in the cortex, or it could simply be the expression of a greater concentration in the tissue of this part as there is for sodium chloride and urea[6].

Table 1. LACTIC ACID MGM. PER CENT GM. OF FRESH TISSUE

Treatment	Cortex mean value	Papilla mean value	Difference ±*S.E.*
$n = 7$	50·93	71·12	20·19 ± 3·55
Water diuresis $n = 7$	54·25	80·29	26·03 ± 3·48
Mannitol diuresis $n = 8$	54·00	108·88	54·88 ± 9·91

It is interesting that under mannitol diuresis the difference increases significantly, although it seems that the cortex–papilla gradient of total concentration tends to decrease in this condition[7]; the greater concentration of lactic acid in the papilla under mannitol diuresis seems therefore to exclude the second hypothesis.

Pharmacological Actions of Some Methoxyindolealkylamines

The O-methylation of catecholamines has been shown to be an inactivation process[1], but the recent characterization of melatonin (N-acetyl-5-methoxytryptamine—a potent agent in lightening frog skin) as a methoxy indole[2] indicates that this may not be true with hydroxyindolealkylamines. To investigate this possibility, we have compared the actions of a number of methoxyindolealkylamines with their corresponding analogues on smooth muscle, blood pressure and behavioural patterns.

Oxytocic activity was measured on isolated œstrous rat uterus. Gramine and its methoxy derivative were found to possess no oxytocic activity at a dose-level as great as 0·1 mgm. per ml. (Values are given as final concentration in the muscle bath.) At the same dose-level, 5-hydroxyindole acetic acid and 5-methoxyindole acetic acid caused small but demonstrable contractions. This action could not be blocked with bromolysergic acid diethylamide (*BOL*). N-Acetyl-5-methoxytryptamine also exhibited slight oxytocic effect, but only at the high dose-level of 0·1 mgm. per ml.

The four other compounds tested were serotonin, bufotenine and their respective methoxy analogues. These exhibited marked oxytocic activity at dose-levels below 10 μgm. per ml. The relative activity of these compounds is given in Table 1, and it can be seen that the methoxy derivatives were only slightly less active than their hydroxy analogues. The results obtained for bufotenine and 5-methoxytryptamine are in general agreement with those of Erspamer[3] and of Barlow and Khan[4].

Whereas N : N-dimethylation of 5-methoxytryptamine only reduces the oxytocic activity slightly, N-acetylation reduces the potency a thousand-fold.

The effect on arterial blood pressure was measured on a smoked drum from a mercury manometer. Two cats and three dogs anæsthetized with pentobarbital were used. The action of compounds was noted before and after the nervous system had been destroyed in cats by pithing, or blocked in dogs by large doses of the ganglioplegic agents : tetraethyl ammonium chloride, 30–40 mgm./kgm., or chlorisondamine ('Ecolid' : 2 mgm./kgm.).

In doses of 1–2 mgm. N-acetyl-5-methoxytryptamine, 5-hydroxyindole acetic acid, 5-methoxyindole acetic acid and 5-methoxygramine had no effect on arterial blood pressure of dogs or cats.

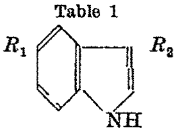
Serotonin, 5-methoxytryptamine, 5-methoxy-N : N-dimethyltryptamine in doses of 0·1 mgm. and bufotenine, 0·5 mgm., all caused depression of arterial pressure or an amphibaric response in both species while the nervous system was intact. After pithing or blocking, these compounds caused blood pressure to rise by 26–92 mm. mercury.

It has been reported that ganglioplegic agents cause powerful augmentation of a variety of pressor agents[5]. Serotonin and 5-methoxy-N : N-dimethyltryptamine were augmented to an almost identical degree, both being slightly exceeded by 5-methoxytryptamine. 5-Methoxytryptamine also exhibited a depressor component, after pithing in cats, usually following a strong pressor phase.

The relative vasopressor potency of these four compounds is : Serotonin > 5-methoxy-N : N-dimethyltryptamine > 5-methoxytryptamine > bufotenine. Thus, O-methylation reduces the vasopressor activity of serotonin but greatly increases that of bufotenine, and N-acetylation of 5-methoxytryptamine inactivates it.

To investigate behavioural disturbance, rats were conditioned to escape, in a shuttlebox, from a 535-V.

Table 1



Compound	R_1	R_2	Oxytocic*	*BOL*†	Effect on blood pressure‡ (unblocked)	(blocked)	Behavioural§ disturbance

5-Methoxy-N : N-dimethyltryptamine	OCH_3	$CH_2CH_2N(CH_3)_2$	0·08	,,	⇅	↑	+++++

* Potency of equimolar concentrations of the base. † Inhibitory effect of *BOL*. ‡ Blood pressure raised ↑, biphasic ⇅. § At 0·1 m*M*/kgm. dose-level each + represents 2 mistakes during 10 tests.

2-m.amp. shock in response to a warning auditory stimulus, individual trials being separated by 6-min. intervals. The criterion of completed conditioning was a correct response to the conditioning stimulus of not less than 9 out of 10 times on two consecutive days. The animals were then used for assay and the number of mistakes plotted against the dose-level. N-Acetyl-5-methoxytryptamine caused no behavioural disturbance at dose-levels of 0·2 m*M*/kgm. At dose-levels between 0·1 and 0·3 m*M*/kgm. 5-methoxygramine caused a somewhat greater degree of disturbance than did gramine. At 0·1 m*M*/kgm., 5-methoxytryptamine, bufotenine and serotonin all gave similar results, though in the case of the latter compound the paresis of the hind legs which developed introduced a physical handicap which modified the interpretation of this result. The most active compound of the series proved to be 5-methoxy-N : N-dimethyltryptamine, which caused 10 mistakes out of 10 trials at a dose-level of 0·05 m*M*/kgm. This was three times more effective than bufotenine, which has been reported to be psychotomimetic in man[6] and to affect the performance of trained rats[7]. At dose-levels exceeding 0·1 m*M*/kgm. the animals given 5-methoxy-N : N-dimethyltryptamine developed rhythmic beating of the forepaws, which tallied closely with the description given by Fabing and Hawkins[6] for the effects of bufotenine in rats which we have, however, not observed. 5-Methoxytryptamine also proved quite potent and in the same range as bufotenine. Finally, 5-methoxygramine appeared to cause more mistakes than did gramine itself.

Thus the ability of gramine, serotonin and bufotenine to cause behavioural mistakes was increased by O-methylation; and whereas N : N-dimethylation of 5-methoxytryptamine increases its potency, N-acetylation inactivated it.

It can therefore be concluded that O-methylation of hydroxyindoles is not an inactivation mechanism as is the O-methylation of catecholamines. The O-methylation of hydroxyindoles, however, changes their activity in the three assay procedures used in the following ways: oxytocic activity is still exhibited though slightly decreased; the vasopressor activity of serotonin is decreased but that of bufotenine is increased; ability to cause behavioural mistakes is increased. In addition, although O-methylation and N-acetylation are both necessary for the frog skin lightening activity of melatonin[2], it is the N-acetyl group which renders melatonin inactive towards smooth muscle, blood pressure and behaviour.

We wish to thank Dr. P. A. Khairallah for his help and Mrs. G. H. Britton for her generous financial support.

HÆMATOLOGY

A Possible Specificity of Albumin Auto-antibodies

ANTI-*I* was the name given by Wiener *et al.*[1] in 1956 to a cold antibody found in the serum of a patient suffering from cold antibody hæmolytic anæmia. Further investigations into the *I* group system were made by Jenkins *et al.*[2], Tippett *et al.*[3], Weiner *et al.*[4] and Marsh[5]. These workers showed that cold auto-antibodies (previously called non-specific cold agglutinins) had *I* specificity and that occasional powerful examples of these antibodies may be found as auto-agglutinins in cases of cold antibody hæmolytic anæmia. The *I* antigen has an almost universal distribution, Wiener *et al.* finding only five *i* people from 22,000 blood donors, while Jenkins *et al.* failed to find an example of the *i* phenotype after testing 17,000 donors. Marsh afterwards described examples of cold auto-antibodies having *i* specificity and showed that normal infants at birth possessed the *i* phenotype, which changed within 18 months of birth to *I*. He concluded that the rare *i* phenotype in adults arose from the absence of a genetically determined factor essential for the proper development of *I*. The majority of cold auto-antibodies therefore appear to have *I* specificity, a minority may be anti-*i*.

In 1956, Weiner *et al.*[6] described some examples of a rare auto-agglutinin active against all cells, but only when they were suspended in bovine albumin. These auto-agglutinins were inactive by anti-globulin or enzyme techniques and could not be absorbed by saline-suspended red cells. We have encountered two examples of the albumin auto-agglutinin described by these workers and were able to test them for *I* or *i* specificity.

Both sera were active against the patient's own cells and also all cells of a large genotyped panel, but only when albumin suspended red cells were used. One serum contained an additional trace of anti-*D* which was successfully removed by absorption with saline-washed rhesus-positive red cells.

The sera were tested against the red cells of two examples of the i_1 phenotype, one i_2 and four cord blood samples, with appropriate adult controls. The tests were all positive with about the same strength of reaction. Repeated tests with one of the sera in titration (using *AB* serum as a diluent) showed that the i_1 and i_2 cells scored the same as the adult controls; the cord samples were slightly weaker.

It is apparent from these results that while cold auto-antibodies have *I* or *i* specificity, albumin auto-agglutinins are not aimed at antigens within the *Ii* system.

Action of Proteolytic Enzymes on the Human Erythrocyte Surface

SEAMAN *et al.*[1] have recently described the liberation of a sialomucopeptide by the action of trypsin on the human erythrocyte surface. Similar results have been obtained by Mäkelä *et al.*[2]. My work concerned with the chemistry of *MN* blood group-active mucoids from human erythrocytes has revealed that N-acetylneuraminic acid-containing mucoids, which carry *MN*-active groupings, were liberated into the supernatant by the action of papain[3]. A review of the *MN* blood group active substances, their isolation and inactivation by several methods has been published elsewhere[4]. Further work led to the examination of other enzymes which are known to inactivate *M* and *N* : trypsin, ficin, bromelin, and stem-bromelain[4]. In all cases the isolation procedure to recover the non-dialysable split products was similar to that described previously[2] for papain-treated red cells, which involved phenol/extraction of the supernatant after incubation with enzyme and centrifugation. Some chemical data of the mucoids obtained are given in Table 1.

Table 1. QUANTITATIVE CARBOHYDRATE VALUES OF MUCOIDS RELEASED BY DIFFERENT ENZYMES

	Trypsin	Ficin	Bromelin	Papain
N-Acetylneuraminic acid (per cent)	19	19	13	14·7
Reducing sugar (galactose) (per cent)	29·4	39·9	73·5	47
Hexosamine (per cent)	9·9	13·9	8·2	18·1

In the case of bromelin and also stem-bromelain a glucose-containing polysaccharide from the crude enzyme is recovered in the final product so that chemical analysis gives carbohydrate values which are too high. Paper chromatography showed in all other samples the presence of galactose, glucosamine, galactosamine and small amounts of fucose and mannose. The same sugars have been detected in other *MN*-active preparations from erythrocyte stroma[3]. Although these mucoids were isolated from human *O* cells, no *H*-activity could be demonstrated by rabbit anti-*H* ; only slight inhibition was observed when tested with anti-*H* extract from *Ulex europaeus*.

The fact that all N-acetylneuraminic acid-containing and *MN* blood group-active mucoids prepared in this way give no inhibition of myxovirus hæmagglutination has been interpreted[4] and may be in accord with the findings that the enzyme-treated cells are equally well agglutinated by mumps- and influenza-virus as are the untreated cells. The *MN* activity of these substances is considerable but not so good as the activity of preparations isolated by a procedure where no enzyme is involved[4]. By the latter method large amounts of the N-acetylneuraminic acid-containing influenza-virus receptor are also obtained[4]. In the light of these observations the lowered electrophoretic mobility of enzyme-treated cells is understandable. On the other hand, it is worth noting that removal of either neuraminic acid or neuraminic acid-containing mucoids renders the cells agglutinable by incomplete antibodies[2,4].

The same method has been successfully used for investigating mucoids released by papain from animal erythrocytes. The substance from bovine erythrocytes has already been described[3,4]. The material from horse cells contains 15 per cent N-glycolylneuraminic acid, 21 per cent reducing sugar, 5·7 per cent hexosamine and inhibits slightly the agglutination of human *O*, *N* cells by anti-*N* extracts of *Vicia graminea* ; whereas that from hog cells has 9·5 per cent N-glycolylneuraminic acid, 33·5 per cent reducing sugar and 11·2 per cent hexosamine. Tests of the treated cells with mumps- and influenza-virus indicated that not all the neuraminic acid-containing mucoids had been removed[4].

Blood Potassium and Sodium of Hereford and Brahman Cattle and some Breeds of Sheep maintained in Florida

INCIDENTAL to other comparative physiological investigations with taurine and zebu cattle[1], it was possible to determine the potassium and sodium content of the erythrocytes of these species by flame spectrophotometry. Although there have been several recent reports concerning potassium and sodium in the blood of sheep and their interesting genetic implications[2], there is a paucity of information regarding these elements in the red blood cells of cattle.

Abderhalden was one of the first to study blood electrolytes of cattle, and more recently Kerr reported findings for six *Bos taurus* cattle. The low potassium and relatively high sodium of the erythrocytes of cattle compared with other species as found by Kerr and Abderhalden have been widely cited in text-books, in spite of their meagre basis. Bernstein[3] has, however, confirmed the results of the earlier workers, but fails to state which types of cattle were used in his work.

Twelve Hereford and twelve Brahman heifers in the sixth or seventh month of gestation, and all approximately the same age, were used in the present work. All animals were under the same management and were kept under identical environmental conditions. All the animals were on an adequate plane of nutrition as described previously[1]. Blood was collected in heparinized tubes from the jugular vein of each of these twenty-four animals and centrifuged under standard conditions with a centrifugal force of 1,500*g*. The force was applied for 2 hr. rather than 30 min. in order to eliminate more of the plasma entrapped between the packed cells. Jennings *et al.*[4] have reported that bovine blood centrifuged under standard conditions for 30 min. still retains some 12·5 per cent of the plasma in the packed cell column ; but Chaplin and Mollinson[5] were able to remove most of the trapped plasma by increasing the time the centrifugal force was applied.

A 1-ml. sample of plasma was first taken from each tube of blood, then the remainder of the plasma and the upper layer of cells were removed and discarded. A small quantity of unwashed erythrocytes were then placed in a clean weighed volumetric flask which was reweighed, and sodium determinations were carried out using a Beckman model *B* spectrophotometer at wave-lengths of 770 and 585 mμ respectively. All results were corrected for dilution and those for the erythrocytes adjusted for weight

Table 1. Potassium and Sodium Content of Bovine Erythrocytes and Erythrocytes and Plasma expressed as m.equiv./l. for Hereford and Brahman Heifers

	Herefords				Brahmans

11	18·6	109	9·0	137	11·7	129	7·0	137
12	27·6	116	11·5	141	8·5	134	6·4	135
×	18·4	113	8·5	141	13·8	123	7·0	140

$$\text{Hereford}\quad \frac{[K^+]_I}{[K^+]_E} = 2{\cdot}16 \qquad \frac{[Na^+]_I}{[Na^+]_E} = 0{\cdot}80$$

$$\text{Brahman}\quad \frac{[K^+]_I}{[K^+]_E} = 1{\cdot}96 \qquad \frac{[Na^+]_I}{[Na^+]_E} = 0{\cdot}88$$

Where $[K^+]_I$ = intracellular potassium and
$[Na^+]_E$ = extracellular sodium

of sample and red cell specific gravity (1·088). All the findings are presented in Table 1 as m.equiv./l.

The Herefords appear to have more potassium and less sodium in their erythrocytes compared with Brahmans, the differences for the potassium being significant at the 1 per cent level. Apart from this, these results further confirm the bovine characteristic of low potassium and high sodium content in red cells. The differences in the plasma electrolytes are small and not significant. The ratios of intracellular to extracellular sodium are similar to those reported by Bernstein[3], but the potassium ratios are slightly lower. Bernstein has shown that the potassium concentration ratio for red cells and blood plasma of the dog and cat is approximately 2, and implies that this small ratio may be explained on the basis of the Donnan equilibrium. The higher concentration ratios for potassium obtained by Bernstein for other species would, however, require extra energy for maintenance. The small differences in the potassium concentration ratios by Bernstein and those reported here could be explained by the differences in preparing the red cells for analysis. It has also been demonstrated that the potassium content of erythrocytes varies to a small degree with the level of dietary potassium[6].

Red cells from 35 ewes were similarly examined for potassium and sodium. Five of these animals were Hampshires, 20 Rambouillets and 10 Florida native ewes. The last-named represent a breed which has developed largely by natural selection in Florida since the time of early White settlement. Only a relatively small population of this breed exists, and it closely resembles a degenerate Cheviot, being much smaller and having an inferior coat when compared with that breed. Doubtless the Cheviot has figured in the background of this local breed; but it is also highly likely that other breeds have been intermingled at various times. Compared with imported breeds in the hot, humid environment of Central Florida these native sheep are much more hardy and more tolerant of the usual parasitic and disease conditions associated with sheep in moist places. The Florida native sheep is also characterized by a significantly higher blood hæmoglobin than imported breeds maintained under similar conditions[7]. Despite a well-defined seasonal pattern in blood hæmoglobin of sheep kept in Florida, the native always has a significantly higher concentration[7].

The blood of sheep has been classified into three different types by Kerr and Evans[2] on the basis of erythrocyte potassium. According to Evans, European sheep possess for the most part only two of these types, but Kerr found the third type well represented in Lebanese fat-tailed sheep. Evans has designated the two types common in European sheep as (*L K*), low potassium, and (*H K*) high red cell potassium. For the most part Evans has analysed whole blood to distinguish the potassium-levels, assuming that plasma potassium is fairly constant. While this is probably true, hæmatocrits vary, particularly in exotic livestock maintained in the lower latitudes. The chances of anæmia due to increased parasitic infestation, lower plane of nutrition or certain types of climatic stress are greatly increased, and it was therefore thought to be more reliable to conduct the analyses for red cell potassium directly on the erythrocytes.

Table 2. Incidence of the (*H K*) Blood Type in Three Breeds of Sheep maintained in Florida and a Comparison with Other Results

	5 Hampshires (per cent)	20 Rambouillets (per cent)	10 Florida natives (per cent)
H K	25	5	30
Evans (ref. 2)	28·7	0	(29·1 Cheviot)

The results for the few sheep examined are outlined in Table 2 and would not be expected necessarily to compare too favourably with other results, due to the small numbers. However, these results agree fairly well with those of Evans and co-workers, and it is interesting to note that the incidence of the *H K* blood type in Cheviots as found by Evans closely resembles that for Florida natives.

PATHOLOGY

Mechanism of Increase of Endotoxin Susceptibility in Animals showing Delayed Hypersensitivity

In recent years considerable attention has been paid to the fact that an increase in susceptibility to the pyrogenic and shock-producing action of bacterial endotoxins could be demonstrated in animals showing delayed hypersensitivity[1].

Chinchilla rabbits were sensitized intravenously with live B.C.G. vaccine at a relatively high dose of 10–20 mgm. wet weight. Their condition was assessed repeatedly within 3–8 weeks after sensitization. We measured the variations of body-temperature during the day, skin hypersensitivity to 2, 0·4, 0·08, and 0·016 μgm. purified protein derivate and systemic hypersensitivity to 5 μgm. purified protein derivate or 20 μgm. heat-killed and twice washed B.C.G. bacilli injected intravenously. The increased degree of susceptibility to the pyrogenic effect of purified[2] *Salmonella paratyphi B* endotoxin was evaluated by determining the threshold doses capable of provoking standard fever reactions. In four independent experiments altogether 61 rabbits were used, and more than 30 normal unsensitized rabbits were used as controls. Only absolutely healthy animals were used, and allowance had to be made for the influence of the season of the year.

Controls generally gave the following results: no skin reactions to the tuberculin test doses, no fever reaction to 5–50 μgm. purified protein derivate and 20 μgm.–5 mgm. doses of killed B.C.G. given intravenously. Initial morning temperatures in the majority of the animals were 39° ± 0·2° C.; afternoon and evening temperatures remained unchanged or increased by less than 0·5 deg. C. Normal fever reaction was approximately + 1 deg. C. within the first 2 hr. after the injection of 1 ml. endotoxin in 10^{-8} dilution.

With test rabbits sensitized with the B.C.G. vaccine, the following results were obtained: different degree of skin hypersensitivity; positive systemic reaction in 62 per cent, negative in 38 per cent, of cases. In general, quite good correlation was observed between the results of the skin and systemic tuberculin reactions.

In 32 per cent of test rabbits the initial body-temperature rose by more than 0·5 deg. C., sometimes even by 1 deg. C., as compared with the average temperatures in controls. In approximately two-thirds of test animals the variations in day-temperature were greater than 0·5 deg. C.; in a quarter they exceeded 1 deg. C.

The pyrogenic endotoxin reaction in 45 per cent of test animals was similar to that in controls; a stronger reaction was noticed in 55 per cent of the animals. In these cases the standard fever reaction was produced by endotoxin doses 2–5 times lower than in control rabbits.

By comparison of all the results from individual animals, we were able to distinguish three well-defined groups among the test rabbits. The first group was characterized by a marked skin hypersensitivity, positive systemic reaction to tuberculin and killed B.C.G., normal initial body-temperature and daily temperature rhythm, and normal endotoxin reaction. A contrasting group consisted of animals exhibiting small skin hypersensitivity, negative systemic reaction, increased initial temperature as well as daily temperature variations, and increased endotoxin susceptibility. The third group gave intermediate results.

After B.C.G. sensitization, the development of specific hypersensitivity, accompanied by non-specific increase of endotoxin susceptibility, would be expected in all rabbits; yet this was not found. The increased susceptibility to endotoxins was not correlated with the degree of specific hypersensitivity, but quite otherwise. This excludes the hypothesis that the systemic tuberculin reaction is not a specific hypersensitivity reaction but that it should be considered as a reaction to traces of endotoxic substances present in tuberculin[3]. Moreover, this hypothesis is also refuted by the quantitative relations observed.

The increased endotoxin susceptibility might be attributed to the summation of irritations which arise in the reaction of hypersensitive cells with the sensitizing antigen persisting in the body. In the course of such a reaction, a partial desensitization of cells takes place and substances possessing pyrogenic and other effects are released[4]. In consequence, the state of unbalanced thermoregulation and increased susceptibility to endotoxins develops, together with a decrease in specific hypersensitivity. In animals where these reactions did not take place, a high degree of specific hypersensitivity is observed, without the non-specifically increased susceptibility. This hypothesis was confirmed in further experiments in which various sensitization doses were used[5]. Specific hypersensitivity and increased endotoxin susceptibility do not appear to be two parallel manifestations of delayed hypersensitivity.

Absence of Thyroid Auto-antibody in Experimental Radiation Thyroiditis

THE association between thyroiditis and thyroid-specific autoantibody, both in man[1] and in animals[2], was established in 1956. There is still controversy as to whether the autoantibody is the cause or the consequence of the thyroiditis or whether, indeed, both thyroiditis and autoantibody are independent results of a single pathogenetic factor. However, it is widely believed that escape of thyroglobulin from the thyroid follicles initiates the development of autoantibody. It has been suggested that in experimental thyroiditis induced by radioactive iodine, the inflammation is a response to the liberation of colloid in the interfollicular stroma[3,4]. We have administered radioactive iodine to guinea pigs in order to determine whether autoantibody is produced in these circumstances. It is known that the guinea pig readily produces thyroid autoantibody when injected intradermally with thyroid extract[5].

Thirty-six adult female guinea pigs were divided into three groups, which were given single intraperitoneal injections of 0·2, 0·4 and 2·0 mc. of iodine-131 per kgm. body-weight, while three further animals received saline injections only. Eleven of the animals given the two lower doses received an additional injection of 8 mc. per kgm. 56 days later, in an attempt to stimulate a secondary antibody response when a primary response was undetectable by the technique used. Sera were tested for tanned cell agglutinating thyroid autoantibody[6] at intervals from one day to 229 days after injection. Animals were killed at intervals, and their thyroids examined histologically.

Those animals given the two lower doses showed no histological evidence of thyroiditis up to 28 days after injection. Animals given 2 mc. per kgm. showed no abnormality of the thyroid when examined from 1 to 5 days after injection, but thyroiditis was present from 7 days onwards. With a dosage of 8 mc. per kgm., there was mild thyroiditis when the animals were first examined at 4 days, progressing to extensive necrosis at 7 days. At this stage, the histological picture in those areas which were not necrotic was that of disruption of the follicles, with intermingling of epithelial cells, inflammatory cells and fibroblasts. With such disorganization of the gland there could be little doubt that colloid had been liberated from the follicles. In the later stages the inflammatory reaction subsided and there was considerable regeneration of thyroid epithelium. The high dose of iodine-131 required to produce thyroiditis is due to the low iodine uptake on diet *S.G.*1 (Oxoid).

In none of the 138 sera examined was there detectable autoantibody. Thus, in spite of the presumed escape of thyroglobulin from the follicles at an early stage in the experiment, the development and regression of thyroiditis occurred without production of autoantibody.

BIOLOGY

Molecular Biology or Ultrastructural Biology?

IT is generally recognized that in the past decade or so we have seen great advances, which are of inestimable value for our understanding of fundamental biology, in the field which is concerned with proteins, nucleic acids, genes, viruses, antibodies, enzymes, etc. It is gratifying to note that several important bodies which are in a position to influence public policy in scientific matters have singled out this field as one requiring increased support.

It is unfortunate, however, that it seems to be becoming usual to refer to this connected series of topics by the name 'molecular biology'. This phrase is only marginally appropriate to any aspect of this area of biology, and is highly inappropriate to the greater part of it. Its most natural application would be to the biology of molecules of the conventional chemical kind, such as those involved in intermediate metabolism, and these are precisely not the types of entity with which the field under discussion deals. The smallest particles with which the new advances have to do may, indeed, be regarded as falling near the upper limit of size of the molecular, and, as for some proteins for example, are open to investigation by, more or less, conventional 'molecular' or chemical techniques. The greater part of the recent advances, however, have dealt with entities which are not defined in chemical terms; for example, genes, cistrons, mutational sites, ribosomes, antibodies, endoplasmic reticulum, and so on; and they have been studied predominantly by such non-chemical methods as those involved in viral and bacterial genetics, induced enzyme synthesis, complementation studies, immunology, ultra-centrifugation, electron microscopy, X-ray spectroscopy, and the like. An attempt to squeeze the whole of this wide front of advance under a title such as 'molecular biology', which places the emphasis on physical and chemical methods of investigation, brings with it the danger that the equally essential biological methods—which are in some respects even more penetrating than our existing chemical methods—will be unduly neglected.

The general characteristic of the field under discussion is, surely, that it is concerned with the analysis of entities, such as genes and ribosomes, which fall in the scale of magnitude lying between those visible with the light microscope and those accessible to conventional biochemical methods. A suitable name for it would be 'ultrastructural biology', which does not carry any particular implication as to the methods of investigation which should be employed. It is urged that this name should be used when the whole of this area of research is being referred to; the phrase 'molecular biology' could be retained, if desired, for that aspect of ultrastructural biology which deals with the chemical and physical study of the configuration of biologically important macromolecules.

Influence of Uterine Position on the Response of the Mouse Embryo to the Teratogenic Effects of Hypervitaminosis-A

WHEN a teratogenic agent is administered to a number of pregnant mammals of a single species under identical conditions of timing and dosage, its effect on the development of the young is by no means uniform. In any individual litter, all, none or a proportion only of the young may be deformed. Even when a highly inbred strain is used, variations in the response to the teratogenic agent may be attributable to differences in the maternal genotype. Such differences cannot, however, be held responsible for the situation in which individual members of a litter develop normally while others are deformed. The differences in response of litter mates must derive either from individual variations in genetic make-up or from environmental factors as yet unanalysed. The present investigation was carried out in order to determine the influence of a single environmental factor, namely, the site of implantation, on the susceptibility of the mouse embryo to the teratogenic effects of hypervitaminosis-A.

Forty female mice of the Strong *A* line were used in these experiments. Brother–sister matings only were used and the onset of pregnancy was determined by the presence of a vaginal plug, the day on which

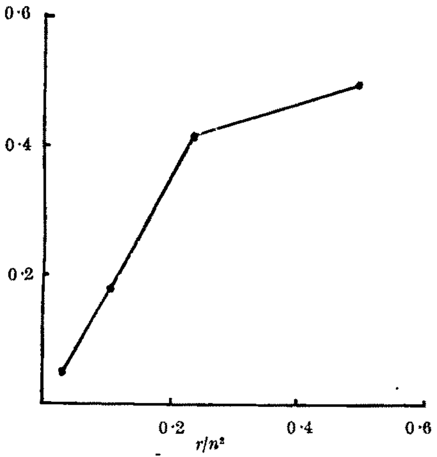

Fig. 1. P is probability of escaping deformity. r is ordinal position of a particular fœtus measured from the vaginal side. n is total number of young in horn. (Both r and n vary from 1 to 8)

the plug was detected being taken as day 1 of the pregnancy. Each animal received 8,000 i.u. vitamin A acetate dissolved in 'Tween 80' (ref. 1) by subcutaneous injection on day 11 of pregnancy. On day 18 of pregnancy all the animals were killed. Each fœtus was examined for the presence of cleft palate, and its position in the uterine horn was recorded.

Statistical analysis of the findings revealed two points of interest. First, fœtuses situated at the ovarian end of the uterine horn were found to be less subject to cleft palate than those at the vaginal end (Fig. 1). Secondly, the probability of cleft palate increased as the number of young in the horn increased.

There are a number of possible explanations for these findings. Since the critical period for the production of a deformity by hypervitaminosis-A is quite sharply defined, the stage of development of an embryo might be expected to have a considerable influence on its response to the teratogenic agent. It is interesting to note, therefore, the observations of Mossman[2] that in the mammalian bicornuate uterus the embryos implanted nearest the oviduct are always more advanced than those at the vaginal end. The weight of the embryo and the degree of development of the placenta at the time when vitamin A is administered are both factors which may play a part in determining whether a malformation does or does not occur. McLaren and Michie[3] found that in the mouse the embryos in the top half of the uterine horn were heavier than those in the lower half at 18½ days *post coitum*.

McLaren and Michie[4] suggested that the blood supply at the site of implantation might be an important factor in determining the occurrence of runting. It is generally agreed that fœtal weight in the mouse varies inversely with the number of young in the uterine horn. The more crowded the horn, the smaller are the individual fœtuses. This may have some bearing on the finding of the present investigation that the highest incidence of cleft palate was in the more crowded horns. It is hoped that estimations which are now being made of the levels of vitamin A in the placenta and liver in normal and malformed litter mates will throw light on the connexion established by the present series of experiments between uterine position and the degree of susceptibility to hypervitaminosis-A.

Our thanks are due to Dr. P. Whittle of the Statistical Laboratory, Cambridge, for the statistical analysis and to Messrs. Vitamins, Ltd., for supplying the preparation of vitamin A. The work was supported by a grant from the Medical Research Council.

Development of Eggs from a Hermaphroditic Sea Urchin

Reports of hermaphroditic sea urchins are not common. For *Arbacia punctulata* six examples are recorded over a period of twenty-five years by Harvey[1]. Since 1956, one report has been made[2].

In the course of work carried out in the summer of 1959, a hermaphroditic *A. punctulata* was found at Beaufort, North Carolina. On being subjected to an electric shock, two gonopores exuded sperm. Eggs were obtained from the remaining three pores. Each pore required individual stimulation in order for shedding to occur, and each gave viable gametes. The eggs were of normal size (80μ) for *Arbacia* collected in this area.

Since unfertilized eggs could be obtained, a study was made to compare the percentage fertilization and the rates of development of self-fertilized eggs and eggs fertilized by sperm from another male. As a control, additional eggs were reserved without sperm. All work was carried out at 23° C.

No indication of fertilization or cleavage was found in the controls. More than 85 per cent fertilization was obtained in both the self-fertilized and cross-fertilized egg batches. All stages of development up to the pluteus stage were directly comparable in both groups, and occurred at the normal rate for this temperature. No abnormal morphology was found.

This work was done during the tenure of a C. W. Hargitt fellowship which I gratefully acknowledge.

Disintegrated Spermatozoa from the Epididymis

In the course of an investigation of the response of spermatozoa in the epididymis of rabbits to the effects of artificial crytorchidism, it was noted that in the controls (that is, 12 normal epididymides on which no operative interference had been undertaken) a remarkable number of immotile decapitated spermatozoa was present in samples withdrawn from regions of the tubule proximal to the cauda epididymidis. Spermatozoa of this kind have been previously referred to as 'disintegrated spermatozoa'[1,2] and presumably indicate a process of degeneration.

In the present work the morphology of spermatozoa was examined in saline-diluted squash preparations under the phase-contrast microscope and in whole specimens. Quantitative estimates of particular characteristics were made from smears after staining with aqueous nigrosin eosin differential stain[3] in order that an estimate of the proportion of 'dead' (eosinophilic) spermatozoa also might be made. In view of this finding, spermatozoa from epididymides of some other species, namely the bull (6 specimens), the goat (2 specimens), the dog (4 specimens) and the cat (3 specimens) were also examined.

In all these cases a proportion of spermatozoa withdrawn from the vas deferens appeared to be degenerate; but it was possible to discern more evidence of disintegration in samples from the body of the epididymis. A variable percentage of dead and decapitated spermatozoa was observed in smears of samples taken from the head of the epididymis and from the initial segment[4]. These percentages were, however, generally lower than those in samples from the body of the epididymis. A relative paucity of degenerate forms from the tail of the epididymis in most specimens was typical. In bovine specimens the overall degree of disintegration of spermatozoa from all levels of the epididymis was comparatively small, but more eosinophilic spermatozoa were present in samples from the body of the epididymis than from any other level, which confirms an earlier report by Ortavant[5]. In both ruminants, differences between the incidence of disintegrated spermatozoa from the body of the epididymis and the cauda epididymidis were not conspicuous. Differences in mean values obtained for the incidence of decapitated spermatozoa from these two areas were, for the bull 8 per cent, and for the goat 16 per cent. In the dog, cat and rabbit, however, the contrast between samples from these two areas was striking, there being many more disintegrated spermatozoa from the body of the epididymis. Differences in mean values obtained between samples from the two parts in each of these species respectively were, 23, 66 and 49 per cent for decapitated spermatozoa, and 36, 63 and 61 per cent for eosinophilic spermatozoa. Despite considerable ranges of variation, differences between estimates from the two levels in these species were plainly significant.

From the observations it is not clear what proportion of disintegrated spermatozoa was due to artefact. The occurrence of disintegrated forms in whole samples where neither staining nor smearing was involved indicates that a number of spermatozoa were degenerate within the intact tubule of the epididymis, and thus some degree of wastage of spermatozoa in proximal regions of the epididymis is apparent. But in stained smears, it is conceivable that separation of the heads in several spermatozoa might have occurred *in vitro* and might thereby represent partly a variation in fragility of the cells at different levels of the tubule. In this connexion, it has been reported that decapitation of spermatozoa in ejaculated semen can be produced by certain methods adopted for the staining and clearing of smears[6]. Alternatively, differences in the viscosity of samples could interfere with the free movement of spermatozoa across the slide and give rise to an increased incidence of decapitated spermatozoa in smeared preparations. Subjectively, the milieu of spermatozoa from the tail of the epididymis appears to differ from that in the more proximal regions, especially in rabbits, and this might be related to possible differences in the effects of handling. Such variation in medium might also allow disintegrated spermatozoa to be obscured in smears of samples taken from the cauda epididymidis due to the effects of a specific distribution of degenerate forms. However, that the highest proportion of disintegrated spermatozoa was found throughout in samples from the body of the epididymis is of interest in that it suggests at least some characteristic quality of the tubular contents at this level. Experiments are now in progress to determine more precisely the inference to be drawn from this surprisingly regular pattern in the incidence of disintegrated spermatozoa from different areas of the epididymis.

Tinsel-type Structure in Flagella of Zoospores associated with Cabbage Clubroot Tissue

PARTIALLY disintegrated clubbed roots of cabbage grown in the greenhouse in soil infested with *Plasmodiophora brassicae* Wor. were stored in a frozen condition for several weeks. They were then macerated in distilled water and much of the coarse debris was removed by filtration of the suspension through several layers of cheesecloth. This was followed by centrifugation at 4,000 r.p.m. for 15 min. and resuspension in sterile distilled water. Centrifugation was repeated three times and after the final one spores were suspended in the nutrient solution described by Macfarlane[1], or in autoclaved tap water in sterile 10 × 75 mm. culture tubes plugged with cotton. Tubes were incubated in the dark at 24° C. or at room temperature. Droplets were examined periodically under a Bausch and Lomb phase-contrast microscope for the presence of motile cells.

The occurrence of flagellated cells in such suspensions was unpredictable, but only one type of zoospore was encountered consistently in preparations from clubbed roots from three sources. Observations indicated that they were anteriorly biflagellate and markedly heterokont. The slightly recurved longer flagellum extended in front of the zoospore as it moved in droplets of the suspension. A much shorter flagellum was usually curved back along the body of the zoospore or extended forward at an angle with the longer flagellum. The zoospores rotated on a longitudinal axis as they moved forward freely and they varied from elongate to pyriform or globose in shape. Active zoospores measured $3 \times 3\mu$–$3{\cdot}9 \times 4{\cdot}8\mu$. A pulsating vacuole was observed in most zoospores. Emergence of zoospores from germinating resting spores was not observed.

Permanent mounts were made using a modified Löffler's stain[2]. Droplets containing motile zoospores were placed on clean glass slides, and the zoospores were killed and fixed by exposure to the fumes of an aqueous solution of 2 per cent osmium tetroxide for 30 sec. The droplets were allowed to dry in a desiccator. Several drops of mordant were filtered on to the dried preparation on the slide, which was heated gently for 45 sec. The mordant consisted of 20 per cent tannic acid, 10 parts; saturated aqueous ferrous sulphate solution, 5 parts; saturated alcoholic basic fuchsin solution, 1 part. The preparation was washed by dipping the slide in a large volume of distilled water. Several drops of stain were then added to the surface of the slide, which was heated gently for 1 min. The stain consisted of a 4 per cent solution of crystal violet in aniline water (2 parts aniline to 100 of water). Excess stain was removed by dipping the slide in several changes of distilled water. After drying in a desiccator, the preparation was mounted in Canada balsam with a No. 1 cover-slip.

Examination of stained preparations with a phase-contrast microscope indicated that the longer flagellum had a rather blunt end and was of the tinsel-type. The shorter flagellum was rounded at the end and bore no appendages. Stained zoospores measured 2·5–4 × 4μ. The long flagellum measured 6–8μ, while the short one measured approximately 2μ in length.

In the preparation of samples for the electron microscope, very small droplets of suspension containing active zoospores were placed on collodion-coated electron-microscope grids, exposed to fumes of 2 per cent osmium tetroxide for 30 sec., and allowed to dry in air. Grids were shadowed with uranium and examined with an *RCA*-type *EMU*2 electron microscope. Examination of such preparations confirmed the nature of the flagella indicated by observations of the stained preparations. A photograph of a typical zoospore taken of an electron microscope preparation is illustrated in Fig. 1 (× *c*. 15,000).

The resting spore suspensions in which these zoospores were observed contained bacteria in varying concentrations, and occasionally flagellate cells other than those described were found. None of these possessed blunt-ended flagella. In one preparation, zoospores were observed which possessed a long flagellum trailing behind the zoospore as it moved. This flagellum was of the whiplash type, and the tailpiece was observed to vary in length as the zoospore advanced. Ellison[3] reported that the two heterokont flagella of primary zoospores of *P. brassicae* appeared blunt-ended without whiplashes or tinsels when stained by the modified Löffler technique. Kole[4] reported that secondary zoospores of *P. brassicae* moved with the longer flagellum trailing behind the zoospore. Zoospores stained by the modified Löffler method showed an apparent whiplash structure of the longer flagellum. The zoospores observed in preparations described here are believed to have developed by germination of resting spores of *P. brassicae*. It would appear from this work that the longer flagellum of the primary zoospore is typically of the tinsel type.

Substrate Specificity of the *Myrothecium* Ascorbic Acid Oxidase

THE substrate specificity of the copper-containing ascorbic acid oxidase of higher plants was studied principally by Zilva *et al.*[1,2]. More recently, Mandels[3,4] discovered an ascorbic acid oxidase in spores of *Myrothecium verrucaria* (Alb. and Schw.) Ditm. ex Fr. which was termed 'atypical' chiefly because it differed from the classical copper-enzyme in substrate specificity and in its resistance to metal enzyme inhibitors. It did not oxidize D-glucoascorbate or D-araboascorbate, and the latter inhibited oxidation of L-ascorbate. The mycelium of *M. verrucaria* also contains an atypical ascorbic acid oxidase, but with properties distinctly different from those of the spore-enzyme as well as of the copper-enzyme[5]. This communication describes the differences in substrate specificities.

The fungal oxidases were extracted from washed mycelial pellets or spores[6] by grinding in an ice bath with a Potter–Elvehjem homogenizer using 100-mesh glass and a *p*H 6·3, 0·01 *M* phosphate–0·005 *M* citrate buffer. This grinding was repeated twice following centrifugation at 0° C. for 10 min. at 1,000*g*. The pooled, cell-free extracts then were centrifuged at 0° C. for 30–40 min. at 20,000*g*. The resulting supernatant was diluted with buffer and stored frozen. Before use, the mycelial extract was acidified with 1 *N* hydrochloric acid to *p*H 4·5, the optimum for enzymatic activity. These fungal preparations showed no cytochrome oxidase or polyphenol oxidase activity. They had high catalase but little or no peroxidase activity. This evidence and the response to inhibitors of iron- and copper-enzymes[3,5] indicated that only ascorbic acid oxidase was involved in the activities measured. The copper-oxidase used was a crude cucumber juice prepared according to Johnson and Zilva[1].

Activity measurements were made at 30° C. in air by standard Warburg procedure at 2 ml. reaction volume, except with the rarer ascorbate analogues when 5-ml. flasks and 0·5-ml. volumes were used. The reaction buffers were 0·034 *M* phosphate–0·017 *M* citrate at *p*H 4·5 for the mycelial oxidase and *p*H 6·0 for the other two. The substrate concentrations used, 0·01–0·02 *M*, were sufficient for maximal velocity on the basis of previous reports[2,4] on the spore and cucumber enzymes and of work in this laboratory[5] on the mycelial enzyme. The concentration of the old samples of ascorbate analogues was based on amount of reduced form, determined by titration with 2,6-dichlorophenol indophenol or enzymatic oxidation with the copper-enzyme. Sufficient glutathione (30–60 μgm.) was added to all reaction mixtures to reduce autoxidation, and suitable autoxidation controls were run when necessary with certain analogues. Activities were based on initial reaction velocities since both fungal enzymes exhibited reaction inactivation[3,5], and rates of oxidation of some substrates also declined after 15–20 min. with the cucumber enzyme. It should be noted that the precision of the assay, particularly on the smaller scale and where autoxidation corrections were necessary, did not establish activity with analogues below perhaps 4–5 per cent of that with L-ascorbate. Thus 0 per cent in Table 1 may represent a low level of activity. The stoichiometry of analogue oxidation, like that of L-ascorbate, was one-half of oxygen uptake per mole of substrate.

Table 1. SUBSTRATE SPECIFICITY OF ASCORBIC ACID OXIDASE OF SPORES AND MYCELIUM OF *M. verrucaria* AND OF CUCUMBER

Substrate	Relative enzyme activity (per cent)* Spore	Mycelium	Cucumber
L-Ascorbate (I)	100	100	100
6-Deoxy-L-ascorbate (II)	0	50	113
D-Xyloascorbate (III)	0	0	65
D-Araboascorbate (IV)	0	38–88	107
L-Araboascorbate (V)	0	0	34
L-Glucoascorbate (VI)	0	90	91
D-Glucoascorbate (VII)	0	0	19
Imino-D-glucoascorbate (VIII)	0	0	0
L-Rhamnoascorbate (IX)	0	98	97
L-Galactoascorbate (X)	0	100	97
D-Galactoascorbate (XI)	0	0	27
Imino-D-galactoascorbate (XII)	0	0	0
L-Guloascorbate (XIII)	0	0	35
Imino-L-guloascorbate (XIV)	0	0	0
D-Erythroascorbate (XV)	0	36–90	100
5,6-Diacetyl-L-ascorbate (XVI)	0	50	83
L-Erythroascorbate (XVII)	0	23	46
Hydroxytetronate (XVIII)	0	88	104
Reductate (XIX)	0	84	62
Methyl reductate (XX)	0	77	46
Reductone (XXI)	0	55	52
Dihydroxyfumarate (XXII)	0	0	0

* Average values except for ranges in case of mycelial enzyme with IV and XV, where activity varied significantly among enzyme preparations.

Of the 22 compounds tested only L-ascorbate (L-xyloascorbate) was oxidized at a significant rate by the spore enzyme (Table 1). Not only are Mandels's results for D-araboascorbate and D-glucoascorbate confirmed, but also it is evident that this enzyme has a very high degree of specificity. Any alteration in the molecule represented in this collection of analogues eliminated activity: (1) change in C-4 configuration, (2) change in C-5 configuration, (3) change in chain length, (4) substitution of hydrogen for hydroxyl on C-6, (5) modification or elimination of the ring, or (6) acetylation of the C-5 and C-6 hydroxyls. The inhibition of L-ascorbate oxidation by D-araboascorbate reported by Mandels[4] also was confirmed. Limited materials permitted only a single test of the other analogues, but it appeared that only 6-deoxy-L-ascorbate and L-galactoascorbate were inhibitory.

The mycelial enzyme was clearly less specific for the L-ascorbate structure (Table 1). Like the spore enzyme, it did not oxidize any of the 6- or 7-carbon analogues (III, V, VII, XI, XIII) with the opposite C-4 (ring) configuration to L-ascorbate. However, it did have some activity toward the 5-carbon analogue (XVII) with the opposite configuration. Among analogues with the same ring configuration, the 7-carbon compounds (VI, IX, X) were oxidized at about the same rate as L-ascorbate, while the rates with the 6-carbon compound (IV) were lower and variable. Substitution of a hydrogen for the hydroxyl group on C-6 of ascorbate (II) or acetylation of the C-5 and C-6 hydroxyls reduced activity to one-half. Removing the side chain (XVIII) or replacing the ring oxygen with a methylene group (XIX, XX) caused only a small reduction in activity. Even the 3-carbon analogue (XXI), with perhaps the simplest possible structure, was oxidized.

Presence of significant amounts of the spore-type enzyme in the mycelial extracts is unlikely, since several of the analogues were oxidized at about the same rate as L-ascorbate. Furthermore, low concentrations (0·0007 *M*) of D-araboascorbate had no effect on the rate of L-ascorbate oxidation by the mycelial enzyme but completely inhibited the spore enzyme.

The results in Table 1 with the cucumber extract were in close agreement with published values[1,2] for the same substrates and include data for a number of compounds apparently not tested before with the copper-oxidase (II, VIII, IX, XII, XIII, XIV, XVII XVIII XX). Analogues with the same ring configuration as L-ascorbate (II, IV, VI, IX, X) were oxidized at about the same rate. Presence of side chain or chain length (VI, XVIII), hydroxyl configuration at C-5 or C-6 (IV, VI, X), and lack of primary hydroxyl at C-6 (II) or C-7 (IX) had no apparent influence on activity. All analogues with the opposite ring configuration (III, V, VII, XI, XIII, XVII) were oxidized, but at a slower rate than L-ascorbate. None of the three iminoascorbates was oxidized, adding support to Dodds's conclusion[7] that a free carbonyl group is essential for activity. Compounds without the lactone ring (XIX, XX, XXI) were oxidized at lower rates, and the transdienol (XXII)[8] was inactive.

Nothing is known of the nature of the active sites of the two fungal enzymes, beyond the fact that these enzymes apparently are not typical copper-oxidases[3–5]. Their specificity patterns, however, give some indication of the substrate groups involved and of the stereochemistry of attachment. The spore oxidase would seem to require a multipoint attachment involving the hydroxyl groups on C-5 and C-6, the dienol group (since it is involved in electron transfer), and possibly the carbonyl group. Lack of a suitable derivative, such as imino-L-ascorbate, has prevented a test of this possibility, but a free carbonyl is required for the copper-enzyme. Such an attachment would be consistent with the absolute stereochemical specificity observed, which involves asymmetric centres at both C-4 and C-5. The highly specific nature of the binding site is also evident from the loss of activity on addition to C-6 of a methyl (IX) or hydroxymethyl group (VI), presumably by steric hindrance. With the mycelial oxidase, substrate structural effects were more quantitative than qualitative. A side chain was not required for attachment or activation, but its configuration (C-4) with respect to the ring was critical. With the unfavourable configuration, only the structure (XVII) with the smallest side chain permitted any activity. Furthermore, with the favourable side chain configuration both the orientation of the C-5 hydroxyl and the presence of the C-6 hydroxyl influenced activity. Thus, the chain hydroxyls seem to participate in binding or to affect the orientation of the substrate at the reactive site.

A clear understanding of the difference in specificity between the spore and mycelial oxidases will require chemical characterization of the prosthetic group(s) and/or the reactive sites. This remarkable change in specificity of an enzyme between two morphological forms of the same organism provides an unusual opportunity to study the factors affecting enzyme specificity.

We are indebted to many people for samples of the rare analogues. This work was aided by a contract with the Office of Naval Research, Department of the Navy, *NR*-103-198, and by a Public Health Service research grant, *RG*-7354, from the Division of General Medical Sciences, U.S. Public Health Service.

'Antibiotic Effects' in Plant Communities

FAILURE of *Araucaria cunninghamii* Sweet. to regenerate in secondary rain-forest dominated by *Backhousia angustifolia* F. Muell. has been observed near Maryborough, Queensland. A plausible explanation of this observation appeared to lie in the widely discussed possibility[1] that a plant may interfere with the establishment of adjacent species in a natural community by releasing 'antibiotics', either from living roots or from decomposing surface debris.

On investigating this hypothesis it has been shown in laboratory tests that substrates, prepared from filter paper treated with *Backhousia* leaf oil, hinder the germination of cress and wheat. Further tests under similar conditions have revealed that dehydroangustione (in this case the major constituent of the oil[2]) hinders the germination of *Araucaria*, the effect varying with the concentration of dehydroangustione in the substrate. Thus, the number of radicles which emerged on substrates containing low (0·1–0·5 per cent by weight) and high (7 per cent) concentrations of dehydroangustione did not differ significantly from the control, but intermediate concentrations (1–5 per cent) caused a significant decrease ($P < 0{\cdot}05$). Normal germination occurred and healthy seedlings developed on substrates containing 0–0·2 per cent dehydroangustione, but toxic symptoms appeared in all other treatments either during germination (1–7 per cent) or after the emergence of the whole seedling (0·5 per cent).

In an attempt to test the ecological implications of this finding, a small area of secondary rain-forest containing a high proportion of *Backhousia* was chosen. Four plots were then selected at random within this area and germination tests (using 200 *Araucaria* seeds per replicate) were set out on both the natural litter and on a litter enriched with freshly gathered *Backhousia* leaves which contained 5·4 per cent of dehydroangustione. A watering treatment was also included in the field test, which was carried out when germination normally occurs in this locality.

If the dehydroangustione present in *Backhousia* litter normally has an adverse effect on the germination of *Araucaria* in the field, it would be expected that any such 'antibiotic effect' would be enhanced under these conditions.

However, germination was virtually complete 37 days after sowing and statistical analysis of the results (Table 1), using the 'arc sine$\sqrt{p}$' transformation, revealed that there was a highly significant *increase* ($P < 0{\cdot}001$) in germination on the litter containing fresh *Backhousia* leaves, compared with that on the natural litter. Moreover, germination on both watered treatments was significantly higher ($P < 0{\cdot}01$) than on the corresponding unwatered treatments. At the conclusion of the experiment, both the unwatered, and watered, enriched litters were recovered from the field. Chemical analysis then revealed that these contained 1·6 and 2·2 per cent by weight, respectively, of dehydroangustione; that is, concentrations within the range found to hinder germination of *Araucaria* in laboratory tests.

This evidence does not eliminate the possibility that in certain circumstances germination of *Araucaria* may be inhibited by the dehydroangustione present in *Backhousia* litter. However, these circumstances have yet to be defined, and an investigation of the microclimatic factors affecting germination and early survival of seedlings in the field appears to be a more profitable line of inquiry.

Table 1

Substrate	Watering treatment	Percentage germination of *Araucaria* after 37 days				
		Replicate				Mean
		(*a*)	(*b*)	(*c*)	(*d*)	
Normal litter	–	9	12	4	14	10*
	+	12	20	6	18	14
Enriched litter	–	20	18	10	19	17
	+	29	25	24	28	27

* In a nearby area the mean germination on an unwatered litter not derived from *Backhousia* was also 10 per cent.

In similar work, Went[3] suggested that the failure of some shrubs growing in the Southern Californian desert to harbour a population of certain annual species is due to the production of toxic substances by the shrubs concerned. This hypothesis was supported by Gray and Bonner[4], who isolated 3-acetyl-6-methoxybenzaldehyde from the leaves of one such shrub (*Encelia farinosa* Gray) and showed that this substance is a potent growth inhibitor in laboratory tests. However, Muller and Muller[5] criticized this interpretation of the field observations on the grounds that extracts of *Franseria dumosa* Gray, which does harbour these annuals, are even more toxic in laboratory tests than extracts of *Encelia*. These authors put forward several hypotheses to account for the failure of the toxic substances to reach an injurious concentration under natural conditions, and suggested that the distribution of these annual herbs may be correlated with the superior water-holding capacity of the mound of organic debris accumulated by *Franseria*, but not by *Encelia*.

The apparently contradictory results of laboratory and field tests in this type of investigation may be due to the fact that all the toxic substances present in the substrate are available to the test species during the laboratory experiment when extracts or milled plant material are used. In our opinion such substrates are not comparable with plant litter, for it has been found in a replicated experiment that *Araucaria* seeds fail to germinate on substrates of milled *Backhousia* leaves enclosed in Petri dishes, but under the same conditions germination is not significantly reduced (although it occurs more slowly than the controls) on substrates of the same intact leaves containing 4·1 per cent of dehydroangustione.

In our opinion, the experiments outlined above emphasize the dangers of arguing, without further experimentation in the field, that the 'antibiotic effects' demonstrated in simple laboratory tests operate in natural plant communities.

Full details of this work will be published elsewhere.

Sorbitol Metabolism in Apple Fruits

Sorbitol is a polyhydric alcohol found commonly in the Rosaceae: in apples it can constitute a large proportion of the dry matter. Little is known, however, of its metabolism in higher plants. Edson[1] referred to a sorbitol dehydrogenase in animals and micro-organisms and mentioned a similar occurrence in plants.

I have been able to show that, when an aqueous extract of an acetone powder preparation from the fruit cortex of apples (var. Miller's Seedling) was treated with sorbitol in the presence of boiled yeast extract, an acid-labile non-reducing sugar was formed. The sugar was probably sucrose and the normal yield was 1–2 mgm. from 10 mgm. sorbitol (at about 20° C.), with due allowance for the sucrose in the yeast extract.

These results were repeatable up to two months after preparation of the acetone powder. It then became inactive, and more detailed examination of the enzyme system involved in this reaction will be made when a further crop of fruit is available.

BACTERIOLOGY

Association of a Steroid and a Pigment with a Diffusible Fruiting Factor in *Myxococcus virescens*

A diffusible factor inducing fruiting-body formation in Myxobacteria has been demonstrated by Lev[1]. In an attempt to identify further such a factor in *Myxococcus virescens*, an aqueous extract of fruiting-bodies was concentrated by drying from the frozen state.

Using a medium which would permit the swarming of vegetative cells, but not the formation of fruiting-bodies, under normal conditions, consisting of 1/100 concentration routine meat-extract agar, with 3 per cent non-nutrient agar and 0·001 per cent sodium chloride, four circular wells were made on a plate supporting a film of vegetative cells, and this was incubated for a further 7 days to obviate any effects of mechanical disturbance. A few drops of extract were placed in two of the wells, with distilled water in the two control wells. After 8 days incubation at 30° C., small fruiting-bodies could be discerned around the wells containing the extract.

Comparison of descending chromatograms of the two extracts showed the existence of a spot on the chromatogram of the fruiting-body extract which was absent from that of the vegetative cells. This spot was associated with the pigment of the fruiting-bodies; it reacted with Liebermann's reagent and is therefore presumed to contain a steroid.

A further experiment in which actual portions of the chromatogram paper were laid on the plate showed that fruiting-body formation was induced in the vicinity of the pigmented spot.

Accumulation of Indole Compounds in Cultures of *Chromobacterium violaceum*

Substances yielding a typical indole test with *p*-dimethylaminobenzaldehyde (Ehrlich reagent) were recently observed in peptone broth cultures of gelatinous strains of *Chromobacterium violaceum*[1]. The nature and the origin of the substances giving the pink-red colour with Ehrlich reagent was of some interest because the species has been reported to lack the enzyme tryptophanase[2] and the genus as a whole is generally considered to be indole-negative[3], which implies inability to degrade tryptophan to indole.

Employing the Ehrlich reagent and technique described by Skerman[4], several cultures of gelatinous *Chromobacteria* were tested for indoles after growth for 5 days at 30° C. in several media. The results shown in Table 1 indicate that the largest accumulation of indoles occurred in 'Bacto' peptone broth containing glucose and incubated under aerobic conditions. 'Bacto' tryptone, which contains more tryptophan than peptone[5], did not allow indole accumulation. When 0·5 per cent (w/v) tryptophan was added to peptone broth no increase in the amount of Ehrlich-positive substances was observed. Synthetic glucose-ammonium salts medium with or without added yeast extract (0·02 per cent) invariably failed

Table 1. FORMATION OF INDOLE COMPOUNDS BY GELATINOUS STRAINS OF *Chromobacterium violaceum*

	Relative intensity of the Ehrlich reaction					
	32		46		11	
Medium	Shaken	Static	Shaken	Static	Shaken	Static
1 per cent peptone	+ + +	+	+ +	+ +	+ + +	+
1 per cent peptone, 1 per cent glucose	+ + + +	+ +	+ + + +	+ +	+ + + +	+ +
1 per cent peptone, 0·1 per cent tryptophan	+ + +	+	+ + +	+	+ + +	+
1 per cent tryptone	–	–	–	–	–	–
1 per cent tryptone, 1 per cent glucose	–	–	–	–	–	–

The cultures were incubated at 30° C. for 5 days in flasks mounted on a rotary shaker (shaken) or in deep tubes (static). Qualitative tests for indoles with Ehrlich reagent produced various intensities of pink colour (+)which were estimated visually. A negative sign indicates that no pink colour was observed.

to support the accumulation of indoles though good growth and pigmentation were usually observed. These results suggest that an abundant supply of amino-acids is a requisite for indole compound accumulation.

Chromatographic examination of glucose–peptone cultures, from which cells had been removed, revealed two substances giving a pink-red colour with Ehrlich reagent. Table 2 shows the R_F values of the substances in three solvent systems and the colour reactions produced when developed chromatograms were treated with reagents commonly used for the identification of indoles. Unless otherwise indicated, the methods and reagents employed were those described by Jepson[6].

Table 2. CHROMATOGRAPHY OF GLUCOSE–PEPTONE CULTURES OF STRAIN 32

	R_F values in			Ultra-violet fluorescence	Colour reactions with				
	A	*B*	*C*		I	II	III	IV	V
Unknown 1	0·90	0·25	0·52	+	o—pk→b	v	r—bn	r	none
Unknown 2	0·72	0·19	0·25	+	pk→b	v	p	r	none
Indole-3-acetic acid	0·92	0·45	0·65	–	pk—p→vg	none	none	none	none
5 OH-indole acetic	0·82	0·25	0·34	+	pk→b	v	r—bn	r	none
Tryptophan	0·24	0·32	0·31	–	v—p	none	none	none	none
5 OH tryptophan	0·56	0·17	0·18	+	lt.b→b	v	r—bn	pk	none

Amounts of 10–20 μl. of cell-free culture fluid were spotted on Whatman No. 1 filter paper strips, and developed in the following solvents : *A*, butanol/acetic acid/water (4 : 1 : 5), *B*, *iso*propanol/ammonia (10 : 1), *C*, butanol/ethanol/water (4 : 1 : 1). Developed and dried strips were sprayed with I Ehrlich, II 1-nitroso-2-naphthol, III sulphanilic acid, IV anisidine, V 2,4-dinitrophenylhydrazine reagent. Colour reactions observed : orange (o), pink (pk), blue (b), purple (p), violet (v), grey (g), red (r), brown (bn).

Chromatography of the unknown substances with a number of known indole containing compounds indicated that the former were not indole, indole-3-aldehyde, indole-3-acetic acid, indole-3-propionic acid, indole-3-butyric acid, tryptophan, 5-hydroxytryptophan, 5-hydroxyindole-3-acetic acid or tryptamine.

Ehrlich reagent is not entirely specific for the indole nucleus, but because of the evidence obtained with other spray reagents, the known substances are believed to be indoles, more exactly hydroxyindoles. Udenfriend[7] has found that 1-nitroso-2-naphthol in the presence of weak acid and a trace of nitrite yields a violet colour with hydroxyindoles but not other indoles. The sulphanilic acid reagent described by Jepson[6] reacts not only with some phenolic acids but also with 4-, 5- or 6-hydroxyindole compounds. The latter also react strongly with anisidine reagent[8] to give an immediate, intense red-brown colour which is also true of the unknown indoles reported here. Phenolic acids do not apparently give the same immediate colour reactions with Ehrlich reagent under the conditions employed for indole detection. A negative test was obtained with 2,4-dinitrophenylhydrazine reagent which indicated the absence of keto- or aldehyde-groups.

Chromatography of peptone broth containing added tryptophan confirmed the observations described above, that is, it neither increased nor decreased the quantity of the two unknown indoles observed in peptone–glucose broth. Tryptophan did, however, give rise to several substances fluorescent in the ultra-violet which gave yellow colours with Ehrlich reagent. It seems clear that tryptophan is not the source of the unknown hydroxyindole compounds.

Chromobacterium species characteristically produce a purple pigment violacein, which has been shown to be a hydroxyindole-derivative[9]. DeMoss and Evans[10] have shown, using strain 553 (American Type Culture Collection), that pigmentation is dependent on L-tryptophan ; in fact they have demonstrated that violacein was produced from the amino-acid by non-proliferating cells, when used as a sole carbon compound in the reaction mixture. These workers and others[11] have shown the hydroxylation of tryptophan to yield 5-hydroxytryptophan to be a major reaction for the amino-acid in this organism and probably is the source of the precursors of violacein.

In the present work L-tryptophan seemed to stimulate neither indole accumulation nor formation of pigment under the conditions used. These observations suggest that the gelatinous strains possess a pathway for synthesis of hydroxy indole compounds and pigment precursors not observed in non-gelatinous strain 553 or other strains dependent on tryptophan for pigment synthesis.

Identification of the hydroxyindoles and their relationship to pigment formation in the gelatinous strains is being investigated further.

I am indebted to the National Institutes of Health, Bethesda, Md., for a grant (*E*–2378).

VIROLOGY

Rous Sarcoma Virus associated with Parthenogenesis in Turkey Eggs

SPONTANEOUSLY occurring parthenogenesis in unfertilized eggs of the domestic turkey, *Meleagris gallopavo* Linnaeus, was first noted[1] at the Agricultural Research Center, Beltsville, Maryland, in 1952. Unselected Beltsville Small White turkey hens, as virgins, produced eggs of which 16 per cent showed parthenogenetic development following an incubation period of 9–10 days. This development consisted chiefly of a thickened sheet of unorganized and often multinucleated cells which covered varying areas of yolk surfaces. Usually, these cells did not attain the degree of organization necessary for blood formation and only on rare occasions were embryos noted. Through a system of selective breeding a strain of Beltsville Small White turkeys has been developed which regularly, as virgins, produce eggs of which 40 per cent can be expected to show some degree of parthenogenetic development. The greatest increase, by percentage, has been in the increased number of eggs showing a high degree of organized development. In 1959, embryos developed in 342 of the 2,926 eggs tested. This represented 11·7 per cent embryos, an increase amounting to 57 times that observed in 1952. Included were 12 poults which were helped from the shell and survived for some time (Olsen[2]).

In 1956, it was reported[3] that the incidence of parthenogenesis in turkey and chicken eggs could be significantly increased with an embryo-propagated live virus vaccine used for the control of the disease, fowl pox. Subsequent tests, at this Center, have confirmed these original observations. In 1958, Stolk[4] reported finding parthenogenesis in viviparous toothcarps following a local infection with the *Ichthyophonus* parasite, the phycomycete *Ichthyophonus hoferi* Plehn-Mulsow.

Work has since been extended to include other virus preparations, using unselected turkeys and observing the incidence of parthenogenesis in their eggs following inoculation. The present communication deals with the Rous sarcoma virus. Thirty unselected Beltsville Small White turkeys, housed in individual cages, were involved in the tests. Eighteen were inoculated subcutaneously in the wing webs with 0·1 gm. equivalent of partially purified Rous sarcoma virus (1 gm. equivalent represents the quantity of virus extracted from 1 gm. of tumour tissue). (I wish to thank Dr. Ray Bryan, U.S. Public Health Service, Bethesda, for the virus extract from chicken tumours.) The other 12 birds, full sisters of those of the treated group, served as uninoculated controls. Eggs from both groups of females were incubated for 10 days before being examined macroscopically for indications of parthenogenetic development. The percentage incidence of parthenogenesis observed over successive 6-day intervals in eggs laid by treated and control birds is presented in Table 1. During the 90-day test period following inoculation, 714 eggs were produced by the 18 treated turkeys, 527 by the 12 control birds. Of all eggs produced by the treated birds, 25·4 per cent showed parthenogenetic development, while 15·9 per cent of the eggs from the control group were so classified. The difference, when tested by the analysis of variance using weighted squares of means, was found to be highly significant at the 1 per cent level. (Thanks are due to Mrs. R. R. Taylor of this Center for this analysis of data.)

Table 1. Percentage Incidence of Parthenogenetic Development observed in Eggs of Beltsville Small White Turkeys following Inoculation with Rous Sarcoma Virus

No. of days following inoculation	Treated birds		Controls (untreated)	
	Eggs tested	Percentage parthenogenesis	Eggs tested	Percentage parthenogenesis
22–27	72	11·1	53	15·1
28–33	69	22·6	52	13·5
34–39	59	20·3	42	16·7
40–45	65	32·3	46	15·2
46–51	65	26·1	50	16·0
52–57	67	35·8	49	10·2
58–63	64	28·6	46	15·2
64–69	74	21·6	50	16·0
70–75	53	15·1	46	26·1
76–81	56	33·9	42	16·7
82–90	70	28·6	51	15·7
Totals and averages	714	25·4	527	15·9

The results presented clearly indicate that Rous sarcoma virus tends to increase the incidence of macroscopically observable development in unfertilized turkey eggs.

Bromegrass Mosaic Virus: a Virus containing an Unusually Small Ribonucleic Acid

CHEMICAL and physical properties of viruses are being investigated in several laboratories in order to obtain structural information which relates to questions of virus synthesis and genetics. Bromegrass mosaic virus, a spherical plant virus, may qualify as a useful test object for such investigations. Data reported here show that this virus is particularly small, and furthermore that the molecular weight of its ribonucleic acid is much smaller than that of any other known virus.

The sedimentation coefficient of bromegrass mosaic virus was measured in a Spinco model *E* analytical ultracentrifuge at 23·3° C. in 0·1 ionic strength buffer (sodium phosphates + sodium chloride, *p*H 6·0) at 35,600 r.p.m. Runs were made at concentrations of 0·12, 0·25, 0·37, 0·49 and 0·99 per cent, and the resulting plot of sedimentation coefficient versus concentration was extrapolated to infinite dilution. The extrapolated value, 92·0 *S*, was corrected to the value expected in water at 20° C. Thus, $s^{\circ}_{20,w} = 86{\cdot}2\ S$. Diffusion measurements were carried out in a quartz Tiselius cell in a Spinco model *H* electrophoresis-diffusion apparatus at 2° C. in the same buffer as above. The virus concentration was 0·42 per cent. Apparent diffusion coefficients were calculated according to the method of Longsworth[1] from five photographs of the Rayleigh fringe patterns taken at selected time-intervals. From these results the diffusion coefficient was calculated to be $8{\cdot}62 \times 10^{-8}$ cm.^{2}/sec., and this value was corrected to that expected in water at 20° C. Thus, $D_{20,w} = 1{\cdot}55 \times 10^{-7}$ cm.^{2}/sec. From the sedimentation and diffusion coefficients at a virus concentration of 0·42 per cent and an assumed partial specific volume of 0·71 ml./gm., the molecular weight of bromegrass mosaic virus was calculated to be $4{\cdot}6 \times 10^6$. To our knowledge this is the lowest molecular weight reported for any virus.

The nucleic acid content of bromegrass mosaic virus was determined by means of the optical method of Englander and Epstein[2], in which the nucleoprotein concentration is determined by a measurement of the refractive index increment of a solution, and the nucleic acid concentration is determined by a corresponding measurement of the optical density at 260 mμ. The measured optical density of the virus solution was corrected for the effect of light scattering and for absorption due to protein. (The extinction coefficient for ribonucleic acid at 260 mμ was taken to be 22·3 cm.^{2}/mgm., the specific refractive increment to be 1·8 × 10^{-4} ml./mgm. and the protein extinction coefficient to be 0·5 cm.^{2}/mgm.) The ribonucleic acid content was found to be 21 per cent. By analogy with the reported characteristics of the ribonucleic acid of other small viruses, it is reasonable to assume that bromegrass mosaic virus ribonucleic acid is all in one piece. Its molecular weight is then 1 × 10^6. This is a lower molecular weight than that of any other known genetically functional nucleic acid[3,4].

Experiments were undertaken to show that the 4·6 million molecular weight particle described above is indeed the infectious virus. These experiments consisted of infectivity and particle assays of fractions obtained by density gradient centrifugation as follows: A 10–40 per cent w/v sucrose density gradient (*p*H 6·5 in 0·1 ionic strength phosphate buffer) was prepared according to the method of Bock and Ling[5]. A 0·25-ml. sample of a 0·53 per cent solution of bromegrass mosaic virus was layered on top of the gradient solution and this was centrifuged at 25,000 r.p.m. for 3 hr. in an *SW*-25 swinging bucket rotor of a Spinco model *L* centrifuge. A single, opalescent band corresponding to the 4·6 million molecular weight particle was observed in the centrifuge tube at the conclusion of the run. The tube bottom was punctured with a hypodermic needle, and 1-ml. fractions were collected and tested for infectivity on the local lesion host *Chenopodium hybridum*[6]. Fractions 1–5, 6–10, 11–15 and 25–29 were pooled. 0·1-ml. samples of the pooled fractions and the remaining fractions 16–24 were brushed on to alternate right and left half-leaves after dusting them with 'Carborundum'. The opposite half-leaves were brushed with a standard bromegrass mosaic virus solution. Adjustment of the local lesion count for difference in susceptibility of leaves was made. Results are shown in Fig. 1. It may be seen that the maximum infectivity coincides with the maximum particle concentration as measured by optical density, and moreover the entire set of infectivity and optical density values superpose very well. Since the separation into fractions was essentially on the basis of sedimentation velocity it may be concluded that the infectious agent sediments at the same rate as does the 4·6 million molecular weight particle.

A similar experiment was performed with a 35–38 per cent w/w rubidium chloride density gradient (same buffer as above). Bacteriophage $\varphi X174$ top and bottom components the particle densities of which in rubidium chloride are 1·32 and 1·40, respectively, were added to the virus solution as markers in order to establish the resolving power of the procedure. The density of the 4·6 million molecular weight particle is intermediate to these two values. After 12 hr. of centrifugation three bands were observed in the density-gradient tube. Infectivity analysis (carried out by Robert K. Fujimura) of appropriate fractions (by plaque counts on *E. coli C*) verified that the optical density in the first band was due to $\varphi X174$ bottom component. The second band contained the 4·6 million molecular weight particle, identified by its intermediate density and distinctive ultra-violet absorption spectrum. The third band contained $\varphi X174$ top component, verified by its distinctive ultra-violet absorption spectrum. Infectivity on *Chenopodium hybridum* showed that only the fractions corresponding to the second band contained infectious bromegrass mosaic virus. Since the particles were separated in this experiment according to their densities, it may be concluded that the infectious agent and the 4·6 million molecular weight particle have the same density.

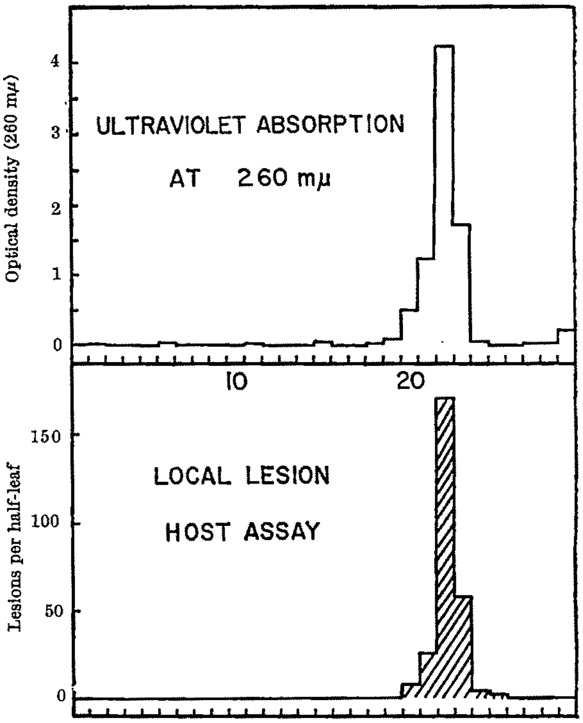

Fig. 1. Ultra-violet absorption at 260 mμ and infectivity assays of fractions obtained from sucrose density gradient (10–40 per cent w/v) centrifugation of bromegrass mosaic virus

Thus, we conclude on the basis of velocity and equilibrium sedimentation experiments that the particle, the characteristics of which we have described, is indeed the infectious virus.

This work was supported by the U.S. Public Health Service and by the Research Committee of the University of Wisconsin Graduate School from funds supplied by the Wisconsin Alumni Research Foundation.

GENETICS

Genetic Studies with *Klebsiella pneumoniae*

GENETIC recombination following conjugation and phage transduction has been reported within and between several groups of enteric bacteria. It was decided, therefore, to look for evidence of genetic exchange in *Klebsiella pneumoniae*, and between this organism and others of the Enterobacteriaceae.

By means of the penicillin selection technique stable auxotrophic mutants were obtained in 17 *K. pneumoniae* strains. Strain *NCTC* 8821 readily yielded unstable auxotrophs with high rates of reversion to prototrophy, and may perhaps carry a mutation factor like that described by Jyssum[1] in strains of *Escherichia coli*. Strain 8821 did not, however, have a high rate of spontaneous mutation to streptomycin indifference.

Attempted transductions, employing 11 *Klebsiella* phages isolated from pooled sewage, gave only one suggestive result : a cysteine auxotroph of strain *NCTC* 8172 was apparently transduced to prototrophy at low frequency. The possibility that the rare prototrophs resulted, however, from transformations by deoxyribonucleic acid present in the crude phage lysate has not been excluded.

Mixed cultivation experiments were carried out according to the method of Miyake and Demerec[2]. These failed to yield any evidence of genetic recombination, occurring at the rate of at least 1 recombinant per 10^7 cells plated, between the different *K. pneumoniae* strains, between *K. pneumoniae* and *E. coli K-12*, HfrH, or *K. pneumoniae* and strain *NCTC 8706* of *Chromobacterium prodigiosum*.

An interesting syntrophic interaction was found between an unclassified auxotroph of *C. prodigiosum* 8706 and some *K. pneumoniae* auxotrophs. When well-washed cells of the *C. prodigiosum* mutant were spread on minimal *A* agar[3] plates, then incubated at 30°, few prototrophic revertant colonies appeared. Numerous reversions arose, however, if this auxotroph were incubated on minimal medium supplemented with a small amount of broth, or if washed mixtures of the *C. prodigiosum* and *K. pneumoniae* auxotrophs were incubated on minimal medium.

I wish to thank Prof. D. G. Catcheside for his advice, interest, and encouragement, and the Agricultural Research Council for the award of a research studentship.

PSYCHOLOGY

Effects of Mental Activity on Vestibular Nystagmus and the Electroencephalogram

MOWRER[1] noted differences in head nystagmus elicited by rotation under conditions of 'excitement' and 'rest' in pigeons. Wendt[2] has indicated that "inward-directed revery states" reduce nystagmus and that the subject must "maintain an environment-directed orientation" to avoid replacement of nystagmus by wandering, autogenous eye movements. The present work was undertaken to ascertain how nystagmus, produced by a standard vestibular stimulus, is modified by different sets of instructions and, further, to determine the effects of these conditions on the electroencephalogram.

Subjects were seated in a light-proof room in the centre of a rotary apparatus, described in detail by Guedry and Kalter[3]. An adjustable biteboard held the subject's head in a standard position and a telegraph key, mounted on the right arm rest, was used as a signalling device. An Offner type *T* encephalogram, secured to the table, permitted the simultaneous recording of encephalograph (from a pair of parieto-occipital leads), horizontal nystagmus, subject key presses and a marker which denoted the periods of acceleration and deceleration. Subjects met three criteria : (*a*) no history of labyrinthine disorder ; (*b*) production of alpha activity when relaxed with eyes closed ; (*c*) quantifiable nystagmus. Of the seven candidates tested, only one was eliminated (due to a lack of alpha production). All subjects had previous turntable experience.

Three tasks were selected : (1) key pressing-signals made by the subject to indicate onset, cessation, and each experience of 90° of subjective rotation ; (2) mental arithmetic-subjects were instructed to divide 80 and each successive quotient by 5, ignoring the external environment, and proceeding as rapidly and accurately as possible (answers were recorded) ; (3) reverie-subjects were told to ignore the environment and simply to relax and daydream without directing their thoughts in any way. The tasks were given in the sequence above and repeated in the same order. The six trials were conducted successively on a single day.

All trials were conducted in the dark with eyes open, head upright, and rotation in a clockwise direction. Each trial began with a 30-second period of rotation at 1 r.p.m. followed by 14·9 sec. of $4 \cdot 5°/\text{sec.}^2$ acceleration to a constant velocity of 12·2 r.p.m. This speed was held for 2 min. before the subject was decelerated at $4 \cdot 5°/\text{sec.}^2$ to 1 r.p.m. After 1 min. of rotation at this velocity, the turntable was stopped and the trial ended. Prior to each trial, subjects alternately fixated markers for calibration purposes. They were located so as to provide horizontal eye sweeps of ±20° to either side of a central fixation point.

The slow-phase amplitude of the nystagmus was measured in centimetres, summed for the 14·9-sec. periods of acceleration and deceleration respectively, and converted to total degrees of slow-phase eye movement. The measurements made were the vertical distances from the peak of each nystagmic beat to the slow-phase base-line of that beat. Durations were calculated from the start of stimulation to the point where the primary nystagmus ended. The data from the encephalograph were tabulated by the 'seconds of alpha' technique, and the scoring covered only the periods of acceleration and deceleration.

Much less nystagmus was present during the daydreaming than during the key pressing or arithmetic trials (Fig. 1). The scored observations were subjected to separate analyses of variance and *t* tests. For acceleration, the conditions did not yield significantly different results. The deceleration results yielded the following significant relationships : (*a*) smaller total

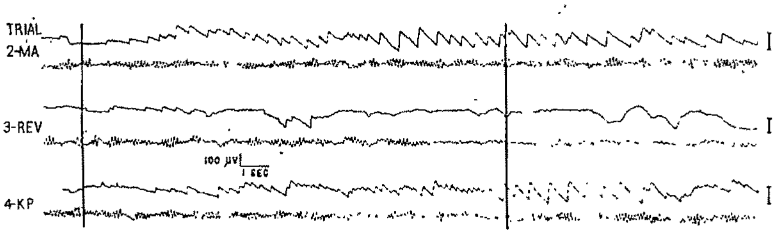

Fig. 1. Nystagmus and electroencephalograph tracings for subject 4 showing trials 2, 3 and 4, with the subject-tasks of mental arithmetic, reverie and key pressing, respectively (paper speed, 25 mm./sec.). The heavy vertical bars demarcate the period of 4·5°/sec.^{2} deceleration of 14·9 sec. duration. The calibrations to the right of each eye movement record indicate 20° eye excursions and the 100 μV. calibration refers to all electroencephalograph tracings. The amplifier time-constant for eye movements was 1·4 sec. Note that the contiguous task is a powerful variable in determining the qualitative as well as the quantitative aspects of nystagmus (during the period of deceleration, $MA = 363$, $REV = 151$ and $KP = 380$ degrees of slow-phase eye movement). The alpha rhythm as well as the nystagmic output are reduced during the reverie condition

degrees of nystagmic output during reverie than key pressing or mental arithmetic (0·03 and 0·001 levels respectively); (*b*) shorter durations of nystagmus for reverie conditions than for key pressing or mental arithmetic (0·01 levels); (*c*) more alpha during mental arithmetic than key pressing or reverie (0·02 levels).

The results demonstrate that nystagmus can vary with type of mental activity, thereby confirming Wendt's claim. However, it does not seem necessary that the subject be 'environment-directed' (as in the key pressing condition) in order to maintain nystagmus. Subjects frequently reported a lack of awareness of acceleration, and more often of deceleration, while doing arithmetic. Although this was also true for reverie states, the nystagmic output remained high during the mental work. Thus, general alertness would appear to be the important factor in maintaining nystagmus.

The failure to obtain significant differences from the acceleration results seems due to a combination of factors. One of these was an alerting 'end effect'. Two of the three subjects who knew the number of trials to be conducted produced more nystagmus during the last acceleration (reverie) than during any preceding trial; the third exceeded all but one previous trial. That such knowledge can 'alert' the subjects and increase the nystagmic output has been noted elsewhere[4]. The remaining factors were deliberately included in the design in order to determine the power of the mental set variable. They included: (*a*) the rapid change from mental activity to reverie required of the subjects; (*b*) the relatively brief period (30 sec.) between instructing the subjects to daydream and initiating the acceleration stimulus. Further work in progress demonstrates clearly that nystagmus declines significantly while subjects are daydreaming during both acceleration and deceleration when more favourable conditions are employed for the establishment of mental 'sets'[5].

It was anticipated that alpha activity would be more evident during reverie and would correlate negatively with nystagmic output. However, more alpha was present during the arithmetic task for the subjects studied here. Although this specific encephalograph finding may be peculiar to the particular group of subjects employed, or to the experimental conditions, the evidence from this investigation and others in progress indicates that: (*a*) nystagmus is markedly sensitive to instructions regarding mental activity while the pattern of the encephalograph is not; and (*b*) vestibular stimulation in combination with various attention-demanding tasks does not block alpha production which is going on[5]. It is frequently stated that various types of sensory input as well as mental activity will block alpha, but other reports note that such is not always the case[6-8].

That gross differences in nystagmic output depended on the mental 'set' of the subject (one subject gave no nystagmus at all during a day-dreaming session) and that this variable is so sensitive as to be manipulated within seconds by simple instructions should be of interest to clinicians seeking to evaluate vestibular dysfunction. It may also explain the lack of a 'constant reaction' and the 'temporary reduction in response' noted for some of the subjects recently studied by Suzuki and Totsuka[9].

Our findings suggest that: (*a*) alertness, whether 'environment-directed' or not, is a highly significant variable in the maintenance of a vigorous nystagmic response; (*b*) subjects should be given objective tasks as a control feature during vestibular experimentation; (*c*) under certain conditions, eye movements may give better indications of a subject's state of alertness than do encephalograph patterns.

The 'Psychological Refractory Phase' and Ageing

When, in psychological experiments, the subject is required to respond as rapidly as possible to a signal closely following another, an increase in response latency is observed[1]. It has become customary to refer to this aspect of high-speed sequential performance as the 'psychological refractory period' in analogy with changes in threshold of neurones, following the propagation of impulses, where the recovery is divisible into an 'absolute' and a 'relative' phase. Welford[1] has argued that the slowing of response to the second of two successive signals is due not to a temporary reduction of central sensitivity, but to the feature that "no two central organizing times can overlap". His view is derived from that of Hick[2], who postulated that in continuous performance the brain is occupied not only in dealing with a particular signal but also with the monitoring of a response to it.

The experiment briefly reported here differs from previous work on psychological refractoriness in three ways. First, the subject was required to deal simultaneously with two streams of signals, one regular, highly probable input (for which a response was made with the non-preferred hand), and the other irregular, with high temporal uncertainty (for which a response was executed with the preferred hand). Secondly, in contrast with most previous experiments, the 'second' signal, when pairs of signals were presented, always occurred after the response to the 'first' signal had been initiated. Intervals of 50, 150, 300 and 600 msec. between the beginning of a regular response and the onset of an irregular signal were employed. Thirdly, the regular signals were presented at two different rates; (*a*) at one every 2 sec.; (*b*) in another session, at one every 4½ sec. 34 subjects, ranging from 20 to 80 years of age, and divided into three age-groups, took part in the experiment. Approximately half the subjects in each group began with the faster rate.

The average response times to the irregular input for the three age-groups are shown in Table 1. (Although omitted to save space, the response latencies to regular signals also decreased with increased rate.)

Table 1. MEAN RESPONSE LAG (MSEC.) TO THE IRREGULAR SIGNAL

Age group	Interval (*R*1–*S*2)			
	50	150	300	600
	At 'fast' rate of the regular sub-task			
20–39 (11 subjects)	319	300	298	307
40–59 (12 subjects)	320	306	292	310
60–80 (11 subjects)	376	356	339	345
	At 'slow' rate of the regular sub-task			
20–39 (11 subjects)	329	295	299	317
40–59 (12 subjects)	358	302	299	323
60–80 (11 subjects)	419	374	364	374

Analysis of these results suggests that the period over which reaction times were lengthened is less than 150 msec. but more than 50 msec. for all subjects at both rates ($P < 0{\cdot}05$—$P < 0{\cdot}001$), and greater than 150 msec. but less than 300 msec. for the middle-aged and older subjects when the regular signals appeared at the faster rate ($P < 0{\cdot}02$). However, the magnitude of the delays is lower than would be predicted on Welford's theory, and it is doubtful if we can, without further qualifications, refer to the range of intervals over which response times increase as the 'refractory period', in the sense of 'dead time'. If the occupation of the central mechanisms by previous signals, or by feedback, prevents the commencement of the processes concerned with the subsequent signal, the response lag should equal the difference between the duration of the 'refractory period' and the time elapsing before the second signal is delivered, that is, it will give a curve with negative slope of 45°. The slopes obtained in the present experiment are considerably less than this in all cases, suggesting that the delays observed may be due not to the start of the processing of the irregular input being prevented, but to the decision mechanism operating less quickly for a short time after it had again become free to deal with signals. Such an interpretation, if correct, implies that the analogy with physiological refractoriness is more exact than hitherto assumed. Possibly it is important to distinguish between an 'absolute phase', in which signal analysis is held up until the central processes already begun have ended, and a 'relative phase' during which the speed of decision is lowered. The duration of both phases is likely to be a function of signal probability, and it is in suggesting this relationship that our results differ from previous ones. Certainly, in our investigation the distinction is of interest, because although for the older subjects an increase in the frequency of regular signals leads to a lengthening of the 'relative refractory period', what can be inferred about the duration of the 'absolute phase' from the slope points to a decrease (mean difference between the two rates × age: at 50 msec. $P < 0{\cdot}02$, at 150 msec. $P < 0{\cdot}05$, at 300 msec. $P > 0{\cdot}05$, at 600 msec. $P < 0{\cdot}02$; mean difference in slopes 50–150 msec. intervals at the two rates: $P > 0{\cdot}05$ for young subjects, $P < 0{\cdot}001$ for both the middle-aged and old groups).

These observations suggest the possibility that amplification of a routine activity may serve, in the case of the older adults, to improve selective responsiveness of central mechanisms to a high-information signal. If such an amplification causes the level of 'vigilance'[3] or 'arousal'[4] to be increased, perhaps via the reticular formation, it is conceivable that decision processes are thereby enhanced. There are, of course, many factors determining the level of activity in the reticular system[5]; but there is direct neurophysiological evidence that one of them may be the rate of sensory inflow[6]. In addition to our observations, the more recent results of comparative experiments[7] would seem to support such an interpretation.

In an attempt to explore these theoretical possibilities, we are now engaged in examining older adults, employing different sensory channels for each stream of signals. Preliminary results suggest that response latencies and refractory delays to visual signals tend to decrease still further with an auditory sub-task. As a further step we are attempting to develop a suitable technique for observing refractoriness in continuous performance, when the size of the ensemble of possible signals varies.

The work is supported by a grant from the Nuffield Foundation. Our thanks are also due to A. C. Staniland for help with the design and construction of apparatus, and to D. J. Stone for statistical advice.

FORTHCOMING EVENTS

Monday, April 10

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m. —Discussion on "Applications of Electrical Phenomena at Liquid Helium Temperatures" opened by Dr. R. E. Hayes.

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. A. E. Canham: 'The Use of Electric Light and Heat in Horticulture".

Royal Aeronautical Society, Historical Group (at 4 Hamilton Place, London, W.1), at 7 p.m.—Discussion Evening—"A Quiz on Little Known Early Aircraft".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. H. W. Tilman: "Voyage to Iles Crozet and Kerguelen".

Monday, April 10—Saturday, April 15

First International Congress on "Metallic Corrosion" (at Imperial College, Prince Consort Road, London, S.W.7).

Tuesday, April 11

British Occupational Hygiene Society (at Birkbeck College, Malet Street, London, W.C.1)—Conference on "Training in Occupational Hygiene".

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Measurement and Electronics Sections (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. D. Woods: "Precision Instruments for Co-axial Line Measurements up to 4 Gc./s.". (Supported by a paper by Mr. D. Woods entitled "The Concept of Equivalent Source E.M.F. and Equivalent Available Power in Signal-Generator Calibration".)

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Prof. M. W. Thring: "Direct Electrical Power Generation by Thermal and Chemical Means".

Tuesday, April 11—Thursday, April 13

Royal Photographic Society, Scientific and Technical Group; Royal Geographical Society; and the British Association for the Advancement of Science (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7)—Symposium on "Photography on Expeditions".

Wednesday, April 12

Institute of Physics and Physical Society, Low Temperature Group (at 47 Belgrave Square, London, S.W.1), at 11 a.m.—Meeting on "Techniques for Generating Very High D.C. Magnetic Fields".

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. L. R. Raymond: "The Petrology of the Permian Rocks of North-east Yorkshire and South-east Durham—The Lower Magnesian Limestone"; Dr. D. K. Bailey: "Intrusive Limestones in the Keshya and Mkwisi Valleys, Northern Rhodesia".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5 p.m.—Dr. R. N. Curnow: "Optimal Programmes for Varietal Selection".

British Institution of Radio Engineers, Electro-Acoustics Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. D. E. Mullinger: "Vibration Analysis and Testing".

Institution of Electrical Engineers, Education Discussion Circle (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Teaching Physics to Engineers", opened by Dr. J. Topping.

Society for Analytical Chemistry (joint meeting with the Oil and Colour Chemists' Association, at the Wellcome Building, Euston Road, London, N.W.1), at 7 p.m.—Scientific Papers.

Women's Engineering Society (at "Hope House", 45 Great Peter Street, London, S.W.1), at 7 p.m.—Miss Sabey: "Road Research".

Royal Aeronautical Society, Graduates' and Students' Section (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Mr. B. S. Shenstone: "Man-Powered Flight—Progress to Date".

Thursday, April 13

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Miss Mary F. Hay, Mr. H. R. Lindner and Dr. T. Mann, F.R.S.: "Morphology of Bull Testes and Seminal Vesicles in Relation to Testicular Androgens"; Mr. T. W. Glenister: "Organ Culture as a New Method for Studying the Implantation of Mammalian Blastocysts".

Institution of Mechanical Engineers; Institution of Civil Engineers; and the Institution of Electrical Engineers (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—H.R.H. The Prince Philip, Duke of Edinburgh, K.G.: "Resources, Human and Material, of the Commonwealth" (Graham Clark Lecture, 1961).

Friday, April 14

Association of Applied Biologists (in the Metallurgy Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 10.15 a.m.—Annual General Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Grade B Assistant to teach Biology to G.C.E. Advanced level and to Pre-nursing classes with some General Science; and a Grade B Assistant to teach Physics to G.C.E. Advanced level and to O.N.C. classes—The Principal, Peterborough Technical College, Easterfield Road, Peterborough (April 15).

Senior Research Scientist (of high academic standing in biochemistry, and preferably with a medical qualification), to take charge of a new laboratory unit and undertake research into the biochemical aspects of cancer—The Secretary, Marie Curie Memorial Foundation, 124 Sloane Street, London, S.W.1 (April 15).

Senior Lecturer in Mathematics—The Principal, Nottingham Training College, Clifton, Nottingham (April 17).

Chair of Zoology tenable in the Durham Division of the University—The Registrar, University Office, 46 North Bailey, Durham (April 22).

Lecturer (preferably with qualifications in historical geography with special reference to Scotland) in the Department of Geography—The Secretary, The University, Aberdeen (April 22).

Research Fellow in Mathematics—The Secretary, Royal College of Science and Technology, Glasgow (April 22).

Senior Lecturer (prepared to initiate research in some branch of pure or applied mathematics) in Mathematics—The Secretary, Royal College of Science and Technology, Glasgow (April 22).

Statistician, Scientific Officer (with a good honours degree in mathematics or science and a knowledge of statistical techniques as applied to agriculture or biology) at the Agricultural Research Council's Unit of Statistics (University of Aberdeen)—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (April 22).

Lecturer in the Department of Physics—The Registrar, University College of North Wales, Bangor, North Wales (April 24).

Lecturer in Cytology in the Departments of Botany and Zoology in the Faculty of Science—The Registrar, The University, Manchester 13 (April 25).

Assistant Lecturer (Grade B) in Geography—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (April 29).

Assistant Mycologist (preferably male, with M.Sc. or B.Sc. degree in botany, forestry or agriculture) at the Forest Research Institute, Rotorua, New Zealand, for the investigation of fungi associated with forest trees and/or fungal taxonomy—The High Commissioner for New Zealand, 415 Strand, London, W.C.2, quoting Ref. B.13/8/1 (April 29).

Assistant Lecturer or Lecturer in Dental Biochemistry—The Registrar, The University, Liverpool, quoting Ref. CV/N (April 30).

Assistant Director (with a recognized degree or equivalent qualification, and a wide experience in agricultural botany or in crop husbandry)—The Director, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (May 1).

Research Fellow (with a minimum of three years postgraduate research experience) in the Department of Chemistry, University College, Ibadan, Nigeria, to join a group working on the chemistry of the West African Flora, in particular to investigate the bitter principles of the West African Cucurbitaceae—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 1).

Research Assistant in Dental Biochemistry, to pursue investigations into the metabolism of bone and teeth—The Registrar, The University, Liverpool, quoting Ref. CV/N (June 30).

Assistant Lecturer, Grade B (with a degree or equivalent qualification, teaching experience, and able to teach to Higher National Certificate standard—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex.

Assistant Lecturer (preferably with a Ph.D. or equivalent postgraduate research experience, and a knowledge of electronics or radiochemistry) in Physical Chemistry—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11.

Assistant Professor (Psychologist) in the University Department of Psychiatry—The Dean of Medicine, University of Alberta, Edmonton, Alberta, Canada.

Biology Technician, to work at the Royal Veterinary College assisting a research fellow of the Zoological Society of London in physiological and animal breeding work—The Assistant Secretary, Royal Veterinary College, Royal College Street, London, N.W.1.

Demonstrators (2) in the Department of Horticulture, to assist with practical classes on vegetable crops and ornamental plants respectively—Prof. O. V. S. Heath, F.R.S., University of Reading Horticultural Research Laboratories, Shinfield Grange, Shinfield, Berks.

Experimental Officer, for work on biochemical problems associated with the diseases of farm animals and the fundamental study of protein and nucleic acid biosynthesis—The Secretary, Agricultural Research Council, Field Station, Compton, near Newbury, Berks.

Graduate Chemist or Physical Chemist (age 23 to 30 years). for work on techniques employed in the fractionation of proteins in human plasma. The work includes the development of laboratory procedures for use on a small production scale—The Secretary, Lister Institute of Preventive Medicine, Elstree, Herts.

Lecturer (with a good honours degree and preferably a higher degree) in Mathematics—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Lecturer (with a special knowledge and/or experience in spectrophotometry and colorimetry) in Physical Chemistry—The Registrar (Department F), Bradford Institute of Technology, Bradford 7.

Lecturers in Geography, Pharmacy, Biochemistry, Inorganic Chemistry, Botany, Mathematics, Physics, Statistics, and Zoology (Comparative Anatomy)—The President, University College, P.O.B. 399, Addis Ababa, Ethiopia.

Master to teach Chemistry to "A" and "S" level G.C.E.—The Headmaster, The Perse School, Cambridge.

Master to teach Mathematics, very largely in the Sixth Form—The Headmaster, Bolton School, Bolton, Lancs.

MINERALOGIST (preferably with Ph.D. degree)—Department of Geology, University of New Brunswick, Fredericton, New Brunswick, Canada.

RESEARCH ASSISTANT (Senior Technician grade, with laboratory experience in chemistry or biochemistry, industrial or hospital), for interesting research in amino-acid metabolism in health and disease—Dr. Woolf, Department of the Regius Professor of Medicine, Radcliffe Infirmary, Oxford.

RESEARCH ASSISTANT (with an honours degree in physiology, physics or a biological subject), for experimental research in human lung function and to assist in teaching—The Finance Officer, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

RESEARCH ENGINEER IN THE DEPARTMENT OF MATERIALS, to assist in setting up and developing a high-temperature research project—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

RESEARCH FELLOW (with a first degree in physics or metallurgy) IN THE DEPARTMENT OF MATERIALS, to undertake research in the fundamental deformation and annealing mechanisms in graphite—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

SENIOR BIOCHEMIST (with an appropriate science degree or the A.R.I.C.) within the Nottingham No. 2 Group of Hospitals, to work under the direction of the Chemical Pathologist at the City Hospital—The Group Secretary, Nottingham No. 2 Hospital Management Committee, Sherwood Hospital, Nottingham.

SENIOR TECHNICIAN or TECHNICIAN (with instrument or physics workshop experience) IN THE RADIOTHERAPY DEPARTMENT, Oldchurch Hospital, for duties which include Physics Workshop, Isotope Laboratory, Radium and Mould Room work—The Group Secretary, Romford H.M.C., Oldchurch Road, Romford, Essex.

SENIOR TECHNICIAN (with experience of normal histological techniques), for work with an electron microscope—The Secretary, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1.

TECHNICAL ASSISTANT (female) IN THE PHYSICS DEPARTMENT, for duties concerned with the medical applications of radioactive isotopes (training will be given in the specialized techniques involved)—The Secretary, Leicester Royal Infirmary, Leicester.

TECHNICIAN (preferably with previous experience in histological techniques) IN THE RESEARCH DEPARTMENT—The Secretary, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1.

PHYSICS

RESEARCH AND DEVELOPMENT IN INDUSTRY

ALTHOUGH in the debate in the House of Commons on the nuclear power programme on February 3 the location of nuclear power plants in Britain was discussed, and some anxiety was expressed over the preservation of amenity, the serious criticism voiced in the latest report of the Nature Conservancy was not mentioned, and the debate dealt with many of the same issues as that on the economic situation which followed on February 6 and 7. These issues are also discussed in the PEP report, *Growth in the British Economy**, to which frequent reference was made in the latter debate. The debate on February 3, centred on a motion of Mr. J. Eden, which was accepted for the Government by Mr. J. C. George, Parliamentary Secretary to the Ministry of Power. The motion urged the Government, while giving due weight to considerations of public safety, the preservation of landscape, and the need to make power available from the cheapest and most efficient sources, to maintain the nuclear power programme at a level that would encourage the development of manufacturing experience and capacity, and provide the best possible prospects for exporting British designs, products and skill. Mr. Eden questioned the wisdom of development proceeding at the rate of about one new nuclear power station a year, and thought that serious waste of man-power and resources was involved in the maintenance of the industrial consortia and in competitive tendering, even by the three consortia now remaining out of five. He was also concerned that some of the stations now under construction might be obsolete fairly soon, and superseded by stations which could be built at lower capital cost and produce power more efficiently. He referred particularly to duplication of research and also asked for more positive encouragement in connexion with exports.

Some of these points were also emphasized by Mr. N. Ridley and by Mr. A. Neave. Mr. Neave referred to the bearing of the load factor, and said that with a load factor of 75 per cent, the cost of nuclear generation might soon approximate to 0·5*d*. per unit. He also urged that the Atomic Energy Authority should make full use of the industrial consortia in the design and development of reactor systems and suggested that, in particular, the Authority should be encouraged to look into new systems, and the advanced conversion of existing reactor systems. He stressed the need for the industry and its technologists to be able to plan ahead with some confidence that the programme would not again be curtailed, but was obviously doubtful whether it is economic to maintain the three industrial consortia, employing altogether some 1,000 scientists and engineers, to produce one station for every three years per consortium. Mr. R. Gunter was also concerned about the effective and economic use of the limited trained man-power in Britain; but Mr. D. Price challenged the view that there is duplication of research and development and thought we should keep at least two of the consortia. It is not easy, he pointed out, to build up again a team that has once been disbanded, and he strongly supported the view that the consortia should be encouraged to participate in development. He thought the area of advance in research on reactor design should be broadened and that, besides associating the consortia more closely with the Atomic Energy Authority, we should make more use of the European Nuclear Energy Agency. Mr. T. H. H. Skeet was concerned more particularly with the design of reactors for export, pointing out that the nuclear power plant of 300–500 MW. produced for the United Kingdom may be too large for some overseas markets.

In replying on the debate, Mr. J. C. George stated that the commissioning of the experimental fast reactor at Dounreay is proceeding satisfactorily; but in regard to controlled thermonuclear reactors, the Authority has broadened its programme of research with a number of experiments aimed at developing the advanced techniques required. He claimed that the present programme, with six nuclear power stations under construction, two more to be started in the next twelve months, and permission sought for another, is sufficient to sustain an industry capable of competing with success abroad and expanding to meet our own needs. He quoted figures for falling costs, from £160 per kW. at Berkeley to £123 at Trawsfynydd and £110 at Dungeness, and said that, besides two stations already sold abroad, there are possibilities of two in India, one in Brazil and one in Japan, apart from the export of research reactors. As regards small reactors, the first might well be on merchant ships, but it does not seem possible, he said, to construct a small nuclear station to provide power at anything like an economic price.

This debate showed that the House of Commons is fully alive to the importance of research and development as a basis in economic growth, and to the need for care to avoid waste of trained man-power. These factors also received some emphasis, though to a lesser extent, when the economic situation generally was debated. Mr. R. E. Prentice, who directed attention first to the wastage of skills, was primarily concerned with this in respect of the re-training of skilled men who had lost their existing jobs, and with apprenticeship; but although he and other speakers referred to the lack of support for the Government's scheme of training young people, no reference was made to the waste caused through the inappropriateness of apprenticeship schemes and the maintenance of periods of apprenticeship which are quite unnecessary under modern conditions. On this point generally, Mr. C. Fletcher-Cooke was forthright, condemning the hoarding of skilled labour, and urging that the skilled labour force should be expanded by putting through group apprenticeship and other means of industrial training with real urgency. He also advocated an intensive study of the whole question of the psychology of the mobility of labour.

* *Growth in the British Economy: a Study of Economic Problems and Policies in Contemporary Britain.* Pp. xii+256. (London: Political and Economic Planning; and George Allen and Unwin, Ltd., 1960.) 30*s*. net.

So far as research and development are concerned, the comments made in the debate related rather to the insufficiency of research in two particular industries, namely, the shipbuilding and machine tool industries, though Mr. S. R. McMaster stressed the need for adequate expenditure on research and development generally as a factor in encouraging higher productivity, and referred to the need to afford adequate support for university research. Both these industries have been the subject of recent inquiry. The machine tool industry was sharply criticized by the Mitchell Committee for its lack of expenditure on research and development, which appears to be a primary reason why imports of machine tools into Britain remain at a high level, and Britain's share of the trade of major importing countries, excluding eastern Europe and China, is less than half Western Germany's and no greater than that of Switzerland. Further, only 1·3 per cent of the employees in the machine tool industry are qualified scientists, compared with figures of 2·2 per cent in electrical engineering, 3·7 per cent in chemical industry and 2·7 per cent in the aircraft industry, and only 0·29 per cent of its technical men are employed on research.

In this comparison, the shipbuilding industry shows up even worse. Only 588 qualified scientists and engineers were employed in the shipbuilding and ship repairing industry at the beginning of 1959—about 0·6 per cent of the number of employees—and Mr. Austen Albu, in a recent broadcast talk on the price of tradition in industry, questioned whether more than 70 or 80 graduates are employed in the shipbuilding and marine engineering industry, and of these more than half are probably employed on Admiralty research. The report from the Department of Scientific and Industrial Research entitled *Research and Development Requirements of the Shipbuilding and Marine Engineering Industries**, which was freely mentioned in the debate, was highly critical of the industry; but the published material has been the subject of some criticism as representing only a part of the report. It was published however, with the concurrence of the Shipbuilding Conference, as representing the shipbuilding and marine engineering industries, and its recommendations have been agreed between that Conference, the Ministry of Transport and the Department of Scientific and Industrial Research. That should assure the implementation of its recommendations; but it is disturbing to find that objections have been raised by the boiler-makers to the comparisons of efficiency in the United Kingdom and elsewhere, and particularly the analysis of labour costs.

Neither here nor elsewhere are closed minds likely to encourage growth in the British economy, and the conclusions of the report are disturbing enough in their brevity. The world shipbuilding industry is itself facing a major and probably prolonged recession, and there is no indication that the United Kingdom industry has on balance any marked technical or economic advantage over its major foreign competitors, apart from its large home market. The total effort at present devoted to research and development in the field of shipbuilding and marine propulsion is insufficient in relation to the serious problems now facing the industry; in particular, practically no organized research has yet been applied to production and management problems with the object of increasing the productivity of labour and capital and reducing costs. While adequate effort is probably being devoted to problems of hull resistance and propeller design, the development of propulsion installations is handicapped by the organizational structure of the industries producing propulsion units and auxiliaries and, in consequence, by the insufficient use of available research facilities.

The figures quoted in this report for the research effort do not quite agree with those given by Mr. Albu. Of the total professionally qualified staff of 1,240, 247 are estimated to be employed on research and development, and the total expenditure on research and development in the industry is estimated at about £1·5 million, or 1·0 per cent of net output. When the contributions made to co-operative research in the British Shipbuilding Research Association, the Parsons and Marine Engineering Turbine Research and Development Association and the British Welding Research Association and to the Ship Division at the National Physical Laboratory are added with the Government contributions, total annual expenditure on research in and for the industry is probably about £2·5 million, or 1·7 per cent of net output; in marine engineering alone, however, it is about £1·9 million, or about 4·4 per cent of net output, a figure which compares favourably with most other manufacturing industries. Nevertheless, there is some evidence tending to confirm that British shipbuilding costs have recently been high by comparison with those of major competitors, and there is no evidence to suggest that over the industry as a whole labour productivity has significantly increased, in spite of increased investment in production plant and machinery. Average construction times in 1957–59 were at least double those in Germany, Sweden and Japan, and it seems certain that the fullest use of shipyard space and capital equipment is handicapped by labour conditions and by the impracticability of shift working.

The report recommends that the Department of Scientific and Industrial Research and the Shipbuilding Conference, in collaboration with the Ministry of Transport, should take further steps to examine the research and development needs of the industry as a whole, and to review the facilities for carrying out research. Arrangements should be made for a concurrent economic and technical study of these needs in marine engineering to provide background for consideration by the Council for Scientific and Industrial Research of the reports it is to receive from the two research associations on their organization and programmes, and this study should be carried out by the Department of Scientific and Industrial Research with the assistance of the Ministry of Transport. The Department and Ministry should also consider with the industry what assistance can most appropriately be given to the industry's own efforts to promote research into production techniques and methods aimed at increasing productivity and reducing costs. As an immediate stimulus to development, the Department of Scientific and Industrial Research should give priority consideration to proposals for development under contract in these industries and with the Ministry of Transport, and the shipping industry should consider what further steps should be taken to study the industry's future technical requirements.

---

* Department of Scientific and Industrial Research. *Research and Development Requirements of the Shipbuilding and Marine Engineering Industries*. Pp. vi+18. (London: H.M. Stationery Office, 1960). 1s. 6d. net.

The President of the Board of Trade, Mr. R. Maudling, in concluding the debate on the economic situation, agreed that research and development generally need expansion. He also expressed the hope that the Mitchell Report on the machine-tool industry would point the way to a considerable expansion of research and development facilities in that industry—the report recommended that the industry's expenditure on research should be trebled. Expansion there and in the shipbuilding industry, however, as well as in nuclear power, needs to be considered in relation to the country's research and development effort generally and to the available resources in scientific and technical man-power. It is clear that the broad question is one to be considered further by the Minister for Science and his Advisory Council for Scientific Policy, for it is in this context that proposals for space research are properly considered, and also the steps to be taken to meet other shortcomings in the research effort of Britain to which the survey carried out for the Advisory Council and outlined in its last annual report pointed.

COLOUR VISION

Mechanisms of Colour Discrimination

Proceedings of an International Symposium on the Fundamental Mechanisms of the Chromatic Discrimination in Animals and Man, held in Paris, 25–29 July, 1958. Edited by Yves Galifret. (Sponsored by the International Council of Scientific Unions.) Pp. viii+296. (London and New York: Pergamon Press, 1960.) 63*s*. net.

THIS book is a report of a very interesting conference at which ten invited papers were given. These introduced a series of valuable discussions which are fully reported. About seventy per cent of the report is in English, twenty per cent in French and ten per cent in German. The topics discussed fall under the following headings: (1) zoological inventory (including a paper on colour vision in insects by Von Frisch); (2) neurophysiological problems (including papers by Rushton on retinal processes and by Galifret on the optic nerve pathways); (3) visual pigments of colour vision: (4) psychophysical problems.

Perhaps the most interesting single issue was the relation between the trichromatic theory (Young. Helmholtz) and the opponent-colour theory (Hering). The exposition of the trichromatic theory (and of its limitations) by Stiles formed an admirably clear statement. Hurvitch gave an interesting exposition of the opponent-colour theory. It was unfortunate that his paper was entitled "The Tetrachromatic Scheme", thereby suggesting that the opponent-colour theory is an alternative to the trichromatic theory. The same information may be analysed (i) in terms of three primaries, or (ii) in terms of (*a*) total luminance (which may be called the white-black difference), (*b*) the red-green difference and (*c*) the yellow-blue difference. The psychophysical data and the electrophysiological observations of De Valois show that both these analyses are 'represented' in the visual cortex. Many other experiments, including the recent work of Svaetchin and MacNicol and of Wagner and Wohlbarst. indicate that signals relevant to both analyses are present at lower levels. It is very probable that eventually the trichromatic and opponent-colour concepts will be seen as aspects of one theory, as has happened with the wave-particle 'conflict' in physics.

Dartnall, who gave a very interesting paper on the biochemistry of cone pigments, opened with the statement that "no-one can say *with certainty* that he has ever had a cone pigment in a test-tube", and although this statement may be a little too cautious, the biochemical side of colour vision is certainly very difficult. Rushton, using biophysical methods, has been able to obtain the absorption spectra of two cone pigments and to show that one is absent in protanopes, but this does not identify the molecular structures.

This is not a book for the general reader. but I recommend it most strongly to all who are working in any part of this field. I would like to record my gratitude to M. Pieron who, as chairman, led the discussions and drew out so many ideas of value. and to M. Galifret both for his own paper and for editing this volume.

R. W. DITCHBURN

RAINFALL IN BRITAIN, 1957

British Rainfall, 1957

Report on the Distribution of Rain in Space and Time over Great Britain and Northern Ireland during the Year 1957 as recorded by about 5,000 Observers. (Ninety-seventh Annual Volume). Air Ministry: Meteorological Office. Pp. iv+245. (M.O. 663.) (London: H.M. Stationery Office, 1960.) 32*s*. 6*d*. net.

THE volume of *British Rainfall* under review is the ninety-seventh of the series and covers the year 1957. It contains the usual tables, charts. and descriptions of the annual, seasonal and monthly amounts of rainfall and numbers of days with rain over Great Britain and Northern Ireland based on observations at 5,022 stations. There are also the usual tables of heavy rainfalls with descriptions of the weather situations in which they occurred.

The general pattern was a decidedly wet first quarter, a very dry second quarter, a wet third quarter and a dry last quarter. The year as a whole had an average rainfall over England but a few per cent more than average over Scotland, Northern Ireland and Wales. Evaporation, too, was about average on the whole with a large value for June, the sunniest since 1909. The largest falls of rain in one day were 6–8 in. over the Camelford area of Cornwall in thunderstorms on June 8.

A new feature in this volume is a snow survey which is for the winter 1956–57 and gives a description of snowfalls and a table of the number of days of snow lying in the mountainous areas.

G. Stanhill, of the National Vegetable Research Station, contributes an article on the variance and co-variance of evaporation and rainfall for seven well-distributed stations, which brings out the importance of taking the variance of evaporation into account in computing the variance of the water content of the soil.

An important change in the main table of stations is the omission of the particulars of the type of gauge to make room for the National Grid reference locating the position of the gauge to the nearest 100 metres. This is a reflexion on one hand of the necessity for accurate knowledge of position in connexion with the more detailed studies of areal distribution of rainfall now required, and on the other hand of the great progress towards standardization of equipment and exposure produced by the much-intensified programme of inspection of gauges by the Meteorological Office.

The preface shows that consideration is being given to the need for continuing the use of such terms as 'rain-day', 'drought', etc., specified arbitrarily in terms of the rainfall amount of one day or a period in view of the possibility of readily obtaining frequency distributions of amounts or spells by the new machine methods of data-processing now coming into use. Comments on this point are particularly invited by the Meteorological Office.

No review of *British Rainfall 1957* would be complete without a mention of the fact that 1957 was the last year of official service of Dr. J. Glasspoole, who joined the British Rainfall Organization in 1916 and was associated with its work for more than forty years.

EXPLORING THE OCEANS

Frontiers of the Sea

The Story of Oceanographic Exploration. By Robert C. Cowen. Pp. 307+21 plates. (London: Victor Gollancz, Ltd., 1960.) 25*s*. net.

IN an expanding branch of science there is a clear need for the good 'popular' book, which can present achievements and aims not only to the general reader but also to scientists in other fields, and may even enable the specialist to see his own work in a truer perspective. Oceanography has been well served by such books in recent years, and that of Robert Cowen is a worthy addition to their number. The author sets out to cover the whole field of marine science, putting present knowledge in its historical setting and indicating the probable lines of future advance. He has achieved success in this comprehensive aim by a balanced selection of topics, which he has treated clearly and vividly.

After a historical introduction, the author discusses present ideas on the origin of the Earth and the oceans. He then describes some of the remarkable new features of bottom relief discovered by recent expeditions. An account is given of the use of oxygen isotope and radiocarbon techniques in the study of sediments and of geophysical methods for probing deeper into the ocean floor. In a chapter on ocean currents, the Gulf Stream is selected as an illustration of the complex structure revealed by modern techniques, and the sub-surface Cromwell Current as one of the major discoveries of recent years. The study of life in the oceans is represented by a chapter on plankton and a brief review of the larger forms of life, giving special attention to deep-living animals.

Having surveyed the present scene, the author looks to the future and to the possibility of exploiting the resources of the oceans, as a source of food and of minerals. In a final chapter on "The New Oceanography", he describes the bathyscaphe, the mesoscaphe and the abyssal submarine, the *Aluminaut*, now being developed. The 'Mohole' project and the problems of the disposal of radioactive wastes at sea are also discussed.

In a book with so many excellent features one is reluctant to look for faults. Some of the line drawings, however, are far from precise, and it would be almost impossible for anyone unfamiliar with the instruments concerned to understand the working of, for example, the water bottles in Fig. 4 or the Kullenberg corer in Fig. 12. There are several factual errors, a serious one being the statement, on p. 201, implying that the nutrient substances account for 6 per cent of the salinity of the sea, an estimate which is too great by several orders of magnitude.

K. F. BOWDEN

HISTORICAL GEOLOGY

Géologie Stratigraphique

Par Prof. Maurice Gignoux. Cinquième édition complétée d'un addendum par Léon Moret. Pp. iv+760. (Paris: Masson et Cie., 1960.) 71 NF

THE data of stratigraphy are in themselves as dry as the dust of the Permian deserts. Undergraduate students of geology often look on stratigraphy as mere meaningless lists of names of formations and of fossils which occur in them. And of course the details of stratigraphy are meaningless unless they are related to specific problems. That is why *Principles of Stratigraphy* by C. O. Dunbar and J. Rodgers has such appeal; it concerns itself with problems of facies interpretation, and the relevance of all the detail is obvious to the reader. Similarly, L. J. Wills's *Physiographical Evolution of Britain* was such a success because the detail was related to problems of diastrophism. Much of the data of stratigraphy is, however, only relevant to problems of the subdivision and correlation of successions, which are problems not in themselves interesting though they may be important in the working out of tectonic structures. It is obviously pointless that the student should burden his memory with excessive detail of this kind. Nevertheless, a certain modicum of general knowledge of successions every student must have; and he does need a text-book to which he can turn for such information when he has to orientate himself in the local setting of a particular problem. Ever since 1926, M. Gignoux's *Géologie Stratigraphique* has been available for this purpose.

It is in many ways a first-class text-book which covers the general stratigraphy of Western Europe very fully and provides also useful information about broad features of the stratigraphy of the rest of the world. Its outstanding characteristic is clarity and simplicity. It can and should be read in French by every student of geology with the least knowledge of the language. It is true that a translation of the fourth edition (1950) is now available. (This fifth edition, published since the death of the author, differs only in having an appendix giving references to a great many recent papers.) But reading this book in French leads the undergraduate student so naturally and painlessly to a knowledge of the French technical terms he will need in reading original papers that it is well worth his trouble.

In its successive editions the book has been considerably extended and continuously brought up to date. Numerous references to original papers cited in footnotes have been added in each edition. In many respects, however, the book does have an old-fashioned look—names like *Glyphioceras*, *Anthraconauta* and *Posidonomya* have not been emended, the Palæocene is not recognized, and the Calabrian (Villafranchian) remains in the Pliocene.

The great feature of this book is its treatment of the Mesozoic and Cainozoic of France and North Africa. There is no better introduction to the complicated stratigraphy of the Alps than can be had from the splendidly lucid sections of successive chapters devoted to this subject. The new appendix to this edition by Prof. L. Moret contains a special section with numerous references to recent literature on the French Alps, with his own critical comments. This is a particularly valuable addition to that part of the book which is of most interest to the non-French reader.

S. SIMPSON

THE JESSE P. GREENSTEIN MEMORIAL SYMPOSIUM

Amino Acids, Proteins and Cancer Biochemistry

Papers presented at the Jesse P. Greenstein Memorial Symposium, Division of Biological Chemistry, American Chemical Society, September 16, 1959. Edited by John T. Edsall. Pp. ix+244. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 7 dollars.

JESSE GREENSTEIN died in 1959 and his scientific publications cover the three decades, 1930–60. All his work carried a sense of building, stone on stone—a painstaking insistence on the surest foundations so that the final result should be as sound as man could make it. He was a pioneer in amino-acid, peptide and protein chemistry all his life and, for many years, was also actively pursuing a vast programme of work on the enzymology of cancer tissues. This dual thread of endeavour running through his life's work was reflected in the contributions to the symposium held in his memory, lending them a coherence which makes their record in this volume a most gratifying one to read.

The first part contains a study by Winitz and other colleagues at the National Cancer Institute extending the series of nutritional experiments using water-soluble, chemically defined diets, which they began with Greenstein in 1957. There are papers on the structure of ribonuclease (Scheraga *et al.*) and of carboxypeptidase *A* (Neurath *et al.*); on the chromatographic evaluation of protein mixtures (Sober and Peterson), and a stimulating contribution by Alton Meister on the activation of amino-acids and the biosynthesis of peptide bonds.

The second part of the symposium stems from Greenstein's interest in cancer research. Weinhouse enlarges on Greenstein's concept of the biochemical uniformity of tumours: that different tumour tissues resemble one another in their biochemical characteristics more closely than they do their tissues of origin. He relates this generalization to a critical consideration of the 'deletion' hypothesis of the cause of cancer and comments on Greenstein's evidence for multiple enzyme deletion in neoplasms, concluding, pertinently, that since so many enzymes appear to suffer deletion after a cell becomes malignant, evidence of far greater cogency will be required before cancer initiation can be ascribed to any specific change of this type.

Roberts and Simonsen, and Saul Kit contribute chapters respectively on the free amino-acids and on the nucleic acids of normal tissues and tumours, and the symposium ends with a fine flurry of fact and speculation over which Racker and Britton Chance preside with easy control. Much of their argument is concerned with the search for a rate-limiting factor in the carbohydrate metabolism of cells, with special reference to the ascites tumour cell. The significance of adenosine diphosphate and of inorganic phosphate in this connexion is expounded and stress laid on the 'compartmentation' of adenosine diphosphate—and of reduced diphosphopyridine nucleotide—into cytoplasmic and mitochondrial forms. A comparable distinction of inorganic phosphate into endogenously formed P_i and slowly diffusible extracellular P_i, underlines the importance of knowing 'readily available' substrate and coenzyme concentrations when considering rate-limiting conditions in the cell. Explanations of both the Pasteur effect and of the well-known phenomenon of lactate production in the respiration of tumours are tentatively given with the aid of the hypotheses outlined. Britton Chance, it must be added, pursues the subject to the point of digital computer representation.

Certain interesting differences come to light in these two chapters, including a basic one on the estimation of hexokinase activities, and another on the effect of glucose on respiring ascites tumour cells (pp. 178 and 199). They may be taken as typifying the general liveliness of the text throughout the book.

"No-one can measure the full impact of the contributions of an outstanding scientist", writes Dr. Edsall in his preface; but those colleagues of Dr. Greenstein who have written in this symposium have finely acknowledged their debt and friendship.

F. H. MALPRESS

Beyond the Planet Earth

By Konstantin Tsiolkovsky. Translated from the Russian by Kenneth Syers. Pp. vi+190. (London and New York: Pergamon Press, 1960.) 15s. net.

WRITTEN in 1920, this mildly prophetic tale is described as a 'scientific fantasy'. It is well above the ordinary run of science fiction, in that the characters behave as normal human beings for most of the time, the laws of physics are also undistorted, and the author was clearly a competent scientist. As to prophecy, the longest shot occasionally finds its mark, and any consistency between fantasy and later fact need not affect its attractiveness as a fable. The preface has a lot to say about Tsiolkovsky's work on rockets, which seems to have been done unobtrusively and unsubsidized, but led to his being named as the "father of the *Sputniks*"; and some other aeronautical priorities seem to have slipped in under this umbrella. The book itself was intended to be entertaining, and is a good story.

The characters are a lively bunch; Franklin, Galileo, Helmholtz, Laplace, Newton, and the inventive Ivanov. They start operations in lush headquarters remote from modern life, which has by 2017, when they start up, become depressing. The base is a castle in the Himalayas (it will be remembered that Jules Verne had already annexed the Carpathians). They work things out, get into orbit, live graciously without gravity, find gold and precious stones on the Moon, and, after some years of resourceful exploration, land happily in the Indian Ocean to start the 'space era' going. The chief re-entry problems are the dreadful colds and influenza to which they succumb on returning to the rigours of ordinary life. A simple and almost unsophisticated story, it has been very readably translated; Mr. Syers has the Arthur Ransome touch.

Technology, Engineering and Safety

Vol. 2. Edited by R. Hurst, R. N. Lyon and C. M. Nicholls. (Progress in Nuclear Energy, Series IV.) Pp. xvi+799+xii. (London and New York: Pergamon Press, 1960.) 105s. net; 15 dollars.

THE present volume is the fourth in a series of eleven, and consists of a selection of thirty-four papers presented at the 1958 Geneva Conference on the peaceful uses of atomic energy, together with a short introduction by C. M. Nicholls. The papers are presented under the following chapter headings: Reactor Chemistry; Reactor Materials; Engineering Experience and Practice; Engineering Studies; and Engineering Aspects of Reactor Safety. The editors have recognized the difficulty of making a representative selection from the large number of relevant papers, and acknowledge that in some cases the choice has been somewhat arbitrary. The book covers a very wide field and includes a number of papers on various aspects of advanced reactors, such as the liquid metal fuelled reactor and molten fluoride systems which do not, however, figure prominently in present-day reactor development programmes. Nevertheless, the information presented forms a useful and interesting record of the considerable research and development work undertaken in support of these ambitious concepts. The eight papers on various aspects of reactor safety form an interesting group, and those dealing with the containment problem constitute a useful introduction to a difficult subject about which there is still a considerable diversity of opinion.

The volume represents a convenient—if somewhat expensive—summary of various aspects of reactor technology and safety, especially for those who do not have ready access to all the Geneva Conference papers. As such, it forms a useful addition to the present series.

High-Energy Electron Scattering Tables

By Robert Herman and Prof. Robert Hofstadter. Pp. ix+278. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1960.) 68s. net.

THIS volume of tables is designed to serve as a handbook for those concerned with high-energy electron scattering. It contains numerical values of nuclear charge density distributions, form factors of nucleons and light nuclei and cross-sections for electron-electron scattering. There is also a number of excellent figures showing point proton cross-sections and other data. The tables are preceded by a review of the theoretical basis of the calculations which may well be of wider interest, as it includes a discussion of Born approximation calculations and their accuracy, the choice of models for nuclear density distributions, and also a more detailed treatment of electron scattering by nucleons and deuterons.

A large part of the work on these topics has been carried out at Stanford University by Prof. Hofstadter and his associates. This book gives further indication of the power of the electron scattering techniques they have developed for the investigation of nuclear structure and sizes.

D. F. JACKSON

The Year Book of the Royal Society of London, 1961

(No. 65.) Pp. 302. (London: The Royal Society, 1961.) 21s.

THE *Record of the Royal Society of London* for 1897 outlines in its preface the purpose of the then newly inaugurated *Year Book* as "containing information which is liable to change". The *Year Book* of the Royal Society is a most valuable compendium for anyone who wishes to keep track of many leading scientists. Much information can be gleaned from its 302 pages, concerning Fellows and Foreign Members, membership of the many committees and boards, standing orders, Council procedure, medal awards, lectures, financial trusts and funds, special memberships and appointments, and a report of Council for the year ended September 30, 1960—a year in which the Society celebrated the tercentenary of its foundation. Appended to the report of Council are twenty-five reports on research work carried out by individuals holding Royal Society research fellowships. Without doubt, the lists of Fellows and Foreign Members is one of the most useful sections of the *Year Book*. However, anyone who is constantly having to refer to this part of the *Year Book* will be well aware that the information available is only valid to January 1, and that continual reference is necessary to the supplementary 'fly-Sheet', when it becomes available. As has been advocated in these pages in previous years, it is to be regretted that publication of the *Year Book* is not withheld until May, by which time it should be possible to include the new Fellows elected in the current year.

INTERSTELLAR AND INTERPLANETARY COMMUNICATION BY OPTICAL MASERS

By Dr. R. N. SCHWARTZ and Prof. C. H. TOWNES*

Institute for Defense Analyses, Washington, D.C.

LONG-RANGE communication by radio-waves is already well known, and the possibility of interstellar communication by radio-waves in the microwave region has been suggested in several interesting proposals[1-3] to search for signals from intelligent beings on planets associated with nearby stars. The supposition is that curiosity such as our own would motivate advanced civilizations associated with stars other than our Sun to make determined efforts to communicate with whatever other intelligent life might exist on neighbouring planetary systems. Radio-waves have, because of our present state of technological development, dominated the field of very long-distance communication, and perhaps for this reason these proposals gave particular attention only to the radio region. It appears, however, that we are now not very far from the development of maser oscillators and other appropriate apparatus in or near the optical region which will also allow detectable light signals to be beamed between planets of two stars separated by a number of light years.

Our own maser techniques in the optical and nearby spectral regions are still in a rudimentary stage; no such operating device was known a year ago[4,5]. Another ten years should bring very marked development. Further, only historical accident seems to have prevented discovery of optical masers thirty or more years ago, in which case they would probably already have been in an advanced stage of development. This implies that a separate civilization might have inverted our own history and become very sophisticated in the use of optical or infra-red masers rather than in the techniques of short radio-waves.

We propose to examine the possibility of broadcasting an optical beam from a planet associated with a star some few or some tens of light-years away at sufficient power-levels to establish communications with the Earth. There is some chance that such broadcasts from another society approximately as advanced as we are could be adequately detected by present telescopes and spectrographs, and appropriate techniques now available for detection will be discussed. Communication between planets within our own stellar system by beams from optical masers appears *a fortiori* quite practical.

Optical Maser Characteristics

Present ruby masers have produced pulsed optical beams of 10-kW. power[6], or still shorter pulses of perhaps 100-kW. peak power. This radiation is concentrated in a band-width of about 0·02 cm.$^{-1}$. Another type of maser, operating continuously at about 0·02 W., emits a wave which has been shown to be in phase over the entire maser reflector surface (about ½ in. in diameter) and to be concentrated in a frequency-interval of about 10 kilocycles per sec.[7]. The latter case is much closer to theoretical expectations[4] for an ideal maser in so far as coherence is concerned. There seems to be no general reason, other than the necessary dissipation of power, why solid-state optical masers cannot operate continuously at high power and with a short-term monochromaticity close to theoretical expectations, or hence with frequency-widths very much less than 1 megacycle/sec.

Now consider directivity of the beam from an optical maser. If a maser produces a wave of wave-length λ with constant phase over a surface of diameter d, the angular width of the radiating beam is approximately λ/d. However, it is obvious that its angular width can be still further reduced if it is operated in conjunction with an auxiliary optical system. Imagine that an ideal lens is put in the beam of focal length d and diameter d. Then, at the focal point the entire beam has a diameter approximately λ. If this focal point is made to coincide with that for a much larger ideal lens or reflecting mirror of diameter D and focal length D or larger, the beam emerges from the latter with an angular diffraction width determined by its aperture, or λ/D. To obtain this result, it is not necessary actually to focus the beam to a small spot; this was assumed only for heuristic purposes. The limiting factors in achieving an intense, directed beam probably reside, not in the source, but in the more familiar technical problems of producing large mirrors of the required accuracy and controlling the optical distortions due to heating by the beam.

For the sake of discussion, two optical maser systems will be assumed with the following characteristics:

System (*a*). Power-level, 10 kW. continuous; frequency, ~ 5000 Å.; band-width, ~ 1 megacycle/sec. or 3×10^{-5} cm.$^{-1}$; diameter of reflector (D), 200 in. (maximum size of present telescopes); beam-width (λ/D), 10^{-7} radian.

System (*b*). A group of 25 masers, each of the same maser characteristics as system (*a*), but with an effective system aperture, D, of 4 in. (and therefore a beam width of 1 sec. of arc, or 5×10^{-6} radian). The entire group is to be pointed in the same direction within the accuracy of the beam-width.

The beam-width of system (*a*) could be attained in a system operating from a platform above (or in the absence of) a planetary atmosphere and of such accurate dimensions that diffraction is the limiting factor. (See following discussion.) When operating from within an Earth-like atmosphere, the atmospheric turbulence restricts the effective band-width to that which would be achievable in a 4-in. telescope system, suggesting system (*b*) in this case as a more reasonable choice.

---

* On leave from Columbia University, New York.

Detectability of Maser Signals

Two primary criteria for detection of a maser beam emanating from near a star are: (1) it must produce enough photons per unit area at the receiver to be detectable with a lens of practical size and in a reasonable time; (2) it must be distinguishable from the background of stellar light.

The maser system operated from above an atmosphere (system (*a*)) would produce a beam of intensity, I, where: $I = \text{flux}/\lambda(D)^2 = 10^{18}$ W./sterad. at 5000 Å. or, per wave-number; $I_\nu = I/\Delta\nu = 3 \times 10^{22}$ W./sterad. cm.$^{-1}$ in a band-width $\Delta\nu = 3 \times 10^{-5}$ cm.$^{-1}$.

The intensity of radiation from system (*b*) would be less by a factor of 100. Under the most favourable conditions, a star of magnitude 8·3 can be seen by the naked eye; hence, the system (*a*) beam could be seen by eye at 0·1 light-year. With ordinary binoculars against the normal sky, the range would be about 0·4 light-year. Corresponding distances would be less by a factor of 10 for system (*b*).

From a distance of 10 light-years, the system (*a*) could be seen visually through the Hale 200-in. telescope or could be photographed with ordinary techniques with an exposure of about 1 min. This time of detection gives about 10^6 quanta of signal, and presumably could be much shortened by special effort. The distance of 10 light-years is significant because, as noted by G. Cocconi and P. Morrison[1], there are seven stars of nearly the same luminosity and spectral characteristics as our Sun within this distance. System (*b*) would require correspondingly about a 1½ hr. exposure in the Hale telescope for detection at 10 light-years. Thus criterion (1) is well satisfied.

The beam intensities indicated here are quite sufficient to communicate between planets of our solar system. They must, of course, compete with a background of light reflected from the planetary surface. The intensity of sunlight scattered by the Earth's surface is less than $1/\pi \times$ cross-sectional area $\times$ solar constant $= 6 \times 10^{16}$ W./sterad., so that the maser beams could be easily seen against the background of the Earth as viewed visually through an optical filter a few hundred angstroms wide, or as a bright spot superimposed on the image of the planet in a telescope of moderate size. This affords an alternate communications technique with some advantages for specific cases over radio communications. For example, because of directivity, light could be beamed from Mars or the Moon to a particular part only of the Earth. Furthermore, equipment for receiving simple signals need not be much more than the human eye.

Consider now the question of detection of such a signal from a distant planet against the background of light from its star. There is some, but little, hope of resolving the two spatially. The Earth and Sun subtend an angle of about ½ sec. of arc at a distance of 10 light-years. Hence light of equal intensity from the two might be resolved at this distance by a telescope of very high quality. However, one can perhaps more easily resort to high spectral resolution in order to discriminate between maser and stellar radiation.

We may take the spectrum of our own Sun as representative of the light to be discriminated against The intensity per unit wave-number of the continuum has a maximum near 5000 Å. of about:

$$I\nu \text{ (5000 Å.)} = 1{\cdot}2 \times 10^{21} \text{ W./sterad. cm.}^{-1}$$

with a total intensity:

$$I = 3 \times 10^{25} \text{ W./sterad.}$$

Here it is seen that the maximum stellar intensity per wave-number is 1/25 that of maser system (*a*) or about four times that of maser system (*b*). The band-width of 1 mc./sec. chosen for the maser might possibly be reduced to increase the relative intensity of maser to star, but possible difficulty in obtaining high-power masers with this stability and some other considerations which will be mentioned later make use of such narrow band-widths unattractive.

For the Sun, I_ν is lower than the value of 5000 Å. by more than an order of magnitude below 2500 Å. and above 15,000 Å., two orders of magnitude below 2000 Å. and above 4μ. Superimposed on this continuum is a discrete structure, the Fraunhofer absorption lines, and emission spectra in the far ultra-violet. The most pronounced absorption lines of Ca II, Sr II and Na provide windows several angstroms wide in which the intensity is less by an order of magnitude than that of the continuum. Of course, it is to be remembered that the Earth's atmosphere limits terrestrial observation to wave-lengths between 2900 Å. and some few microns.

A logical selection in transmission frequency would be either to use a frequency as far in the violet as atmospheric absorption permits, or to pick a prominent Fraunhofer line (as the Ca II *H* or *K* line). In either case, a gain by a factor of about 10–20 in the ratio is to be had over transmission at 5000 Å., the choice probably being dictated by the availability of a suitable maser material to produce the desired frequency. Were it only a question of the solar intensity, another two or three orders of magnitude could be gained by recording above the Earth's atmosphere in the 1400–1800 Å. region. However, the loss of reflecting power in mirror systems and the anticipated difficulties in maser operation at these wave-lengths make the region unattractive—even if recording above the atmosphere were not already too awkward. The advantages of transmission in the infra-red over that at 5000 Å. would be offset by the widening of the beam were diffraction the limiting factor as in system (*a*).

Assuming a maser system (*a*) operating, say, within the Ca II *H* or *K* absorption lines, the ratio of maser to Sun intensity is about 300 in the narrow band-width of 3×10^{-5} cm.$^{-1}$. A spectrometer with resolution comparable to 0·01 cm.$^{-1}$ (that is, somewhat better than a resolution of 10^6 at this frequency) would give a maser signal just equal to the stellar background. Present grating spectrographs of high speed and resolving power give a resolution close to this figure (for example, the echelle spectrograph of G. Harrison[8]). The use of interferometric techniques can provide a resolution of a few orders better than this. An instrument comparable to the coudé spectrographs developed for use in conjunction with the Hale 200-in. telescope and with the required resolution appears capable of producing an acceptable photographic image with an exposure of a little more than an hour. Much less resolution than 0·01 cm.$^{-1}$ would still yield signals detectable against background, although the maser signal would then not be so obviously narrower than some spectral emission lines.

Maser system (*b*) would give an intensity just three times that of stellar background, again in the band-width 3×10^{-5} cm.$^{-1}$. While convenient detectors operating within such a narrow band-width might be developed, none is yet available. A spectrometer of resolution 0·01 cm.$^{-1}$ would afford a maser signal 1 per cent as large as background, which might allow marginal discrimination.

One must consider the possibility that changes in Doppler shifts during the period of exposure will be larger than the spectral resolution used and thus weaken the image. The Earth's orbital or rotational motion, the orbital motion of a satellite around the Earth if such is used as an instrument platform, and corresponding motions of the transmitting source may all produce Doppler shifts which can change the frequency and smear out the maser signal. The maximum rate of variation of the fractional change of frequency due to a Doppler shift $\Delta\nu_D$ from a signal source following a circular path of radius r with angular speed ω is given by:

$$\frac{1}{\nu}\left|\frac{d(\Delta\nu)_D}{dt}\right|_{\max.} = \frac{\omega^2 r}{c}$$

where ν is the frequency and c the velocity of light. Taking the motions within our own solar system as illustrative, one obtains maximum values of 2×10^{-10} per sec. for an Earth-based transmitter mainly due to rotation of the Earth and 10^{-11} per sec. for a Moon-based transmitter. For these Doppler changes on both the receiving and sending end of the transmission to be contained within the required limits of resolution of 0·01 cm.$^{-1}$, the times of photographic exposure in the visible spectrum, then, would be restricted to about an hour. This is, as already noted, the approximate time needed for a good spectrum if the transmitter were at a distance of 10 light-years. Alternatively, both sender and receiver might, of course, compensate for his own cyclical Doppler shifts, which would be well known to him.

The question of exposure, or integration time, has a different connotation depending on whether the observer is engaged in a search of the spectrum or has found a likely line. In the first situation, hundreds of angstroms of the spectrum can be examined in a single photograph and, consequently, the spectral search of a given star is not unduly hampered by fairly long times of exposure. The spectral line sought can be expected to be exceptionally narrow, at an abnormal frequency for the type of star in question, and varying in intensity. Observation of any of these characteristics should lead to closer examination. Once a likely line has been located, a photo-detection system of higher sensitivity could be used to reduce the required integration times to minutes for the purpose of recording modulations in the signal. Actually, with a 200-in. telescope and an efficient dispersing system, the modulation could be visible to the eye.

Discussion

Thus, it appears that if one postulates the existence of an optical maser system beamed towards us of the characteristics of system (*a*) at a distance of the order of 10 light-years, it is within the state-of-the-art for us to detect it. System (*b*) is marginally detectable, or detectable with good signal to background, if very narrow-band optical receivers are developed. One should hence consider the feasibility and expense of such systems as judged by our own experience, and of course in the light of any fundamental difficulties.

Advantages accruing from the coherence of radiation over a very large aperture, or from the theoretical possibility of obtaining coherence among several maser sources are nullified if the system is required to operate from within an Earth-like atmosphere. In this case, system (*b*) above, perhaps augmented in either power-level or numbers of system elements, appears most advantageous. An appreciable increase in the number of elements would not necessarily involve prohibitive expense. Accepting a criterion of minimum detectability as a signal of only 1 per cent of the background, system (*b*) as defined would be sufficient for the job. An added difficulty in working within an atmosphere should be noted. Local air turbulence caused by hot lens and mirror surfaces in contact with the atmosphere would widen the beam even more unless well controlled. The power density reflected from the mirror surface of system (*a*) is close to that of direct sunlight. Such problems, connected with handling a large amount of power in a carefully controlled optical system would probably be some of the most troublesome ones.

The unique advantages of maser sources can be better utilized in operation from a very high-altitude balloon, a space platform, or natural Moon—a possibility that may not have been seriously considered a few years ago but should be more acceptable to-day. The capability of the ideal system (*a*) could possibly be met by using a single large mirror, although the very large mirrors with which we have had experience have not attained the highest angular resolution possible (the Hale 200-in. has an angular resolution of about 1/3 sec. of arc (ref. 9)). The task of obtaining the limit imposed by diffraction may be a difficult one. However, the beam intensities of system (*a*) might also be met by a bank of smaller mirrors of higher accuracy, perhaps operated in phase (the beam intensity varies in such case as the square of the number). In this connexion, it should be noted that the 36-in. mirror to be used in the current *Stratoscope II* high-altitude balloon programme[10] is a casting of fused quartz which is expected to achieve its theoretical angular resolution of 1/10 sec. of arc.

It may be both an encouraging enlargement of possibilities, and at the same time an unwelcomed complication, to find that the frequency of the hydrogen line in the micro-wave region is not the only reasonable place at which to search for possible interstellar communications, and that the optical region also seems a logical one. What other methods are we overlooking which might appear natural to some other civilization? Far ultra-violet and infra-red are absorbed by most imaginable atmospheres friendly to life, and hence would be avoided unless reception above the atmosphere is to be expected. Beams of charged particles would be subject to inconvenient bending in interstellar fields. We see no way of producing neutron beams or electromagnetic waves much shorter than the ultra-violet[4] with adequate intensity. On the other hand, the rapid progress of science implies that another civilization, more advanced than ourselves by only a few thousand years, might possess capabilities we now rule out—they may have already been able to send us an exploratory instrumented probe. Since none has yet been seen, perhaps it would be appropriate to examine high-resolution stellar spectra for lines which are unusually narrow, at peculiar frequencies, or varying in intensity.

Note added in proof. Dr. W. S. Boyle and Dr. R. J. Collins have independently arrived at similar conclusions (private communication).

A PROPOSED DUAL NEUROHUMORAL ROLE OF ACETYLCHOLINE: ITS FUNCTIONS AT THE PRE- AND POST-SYNAPTIC SITES

By GEORGE B. KOELLE

Department of Pharmacology, Schools of Medicine, University of Pennsylvania,
Philadelphia 4, Pennsylvania

ACCORDING to the generally accepted concept of neurohumoral transmission, the arrival of a conducted nerve impulse at the presynaptic terminals of a cholinergic fibre causes them to liberate acetylcholine, which then diffuses across the exceedingly narrow (50–200 Å.) synaptic gap and combines with specific receptors at the postsynaptic site; the combination results in the production of a localized postsynaptic potential, which, if excitatory, triggers off a propagated nerve action potential[1]. In non-cholinergic fibres, other transmitter agents are considered to take equivalent roles; although several naturally occurring substances have been proposed as such, the only other neurohumoral agent which has been demonstrated reasonably convincingly is norepinephrine as the transmitter of the adrenergic postganglionic sympathetic fibres.

From the foundations laid by Loewi, Dale, Feldberg and their collaborators, subsequent work has largely confirmed the foregoing hypothesis. It has, moreover, provided the basis for explaining the mechanisms of action of several classes of drugs, particularly those acting on the peripheral divisions of the autonomic nervous system, its effector organs, and the motor end-plate of skeletal muscle. However, several observations in various laboratories, including my own, during the past few years, while not entirely inconsistent with the hypothesis, cannot be fully explained by it as presented above. The working hypothesis proposed here to explain these phenomena is that the acetylcholine mobilized by a conducted presynaptic impulse may act at two sites: postsynaptically, as outlined above, but prior to that at the presynaptic terminal itself, to bring about the release from the terminal of sufficient additional acetylcholine or of some other neurohumoral agent to initiate the characteristic postsynaptic effect. The proposed action of acetylcholine at its site of liberation is equivalent to its long-postulated role as a local hormone in smooth muscle and other tissues.

There is little claim to originality in the present proposal: it has been invoked in part before, directly or indirectly, to explain isolated phenomena. However, it is believed that the evidence which follows is now sufficient to present it as a general concept.

Histochemical Distribution of Acetylcholinesterase in Nervous Tissue

Determinations conducted on homogenates of various neural tissues have shown that, with certain exceptions, there is fairly good correlation between the concentrations of choline acetylase, acetylcholine and acetylcholinesterase, and that all three entities are present in relatively large amounts in cholinergic neurones (see ref. 2 for references). With the development of a microscopic histochemical technique for cholinesterases[3], and its subsequent modification to permit selective localization of acetylcholinesterase[4,5], it was possible to demonstrate that, in the cat, known cholinergic neurones (for example, anterior horn cells, preganglionic autonomic neurones) contain high concentrations of acetylcholinesterase throughout their entire lengths, whereas adrenergic neurones (for example, the great majority of those in the superior cervical and stellate ganglia) contain scarcely detectable concentrations. All the neurones of the parasympathetic ciliary ganglia are heavily stained for acetylcholinesterase; consequently, the small number of heavily stained neurones of the sympathetic ganglia were considered to be those giving rise to the cholinergic fibres to the sweat glands and the cholinergic vasodilator fibres. On the other hand, a limited number of cat sympathetic ganglion cells show intermediate staining, an observation which has been confirmed quantitatively by Sjöqvist and Holmstedt[6]. Likewise, the sensory neurones of the dorsal root ganglia, which are generally considered non-cholinergic, show intermediate grades of staining[5]. In the rabbit and monkey, in contrast to the cat, the differences between the autonomic cholinergic and adrenergic neurones are not nearly so pronounced; all the latter appear to contain relatively low but appreciable concentrations of acetylcholinesterase; again, concentrations in the sensory neurones in these species are intermediate[5]. The same situation was found in the brain of the rat[7]: all neurones giving rise to somatic motor fibres (for example, the hypoglossal nucleus) and parasympathetic preganglionic fibres (for example, the Edinger–Westphal nucleus) and those of certain correlation centres (for example, the amygdaloid and caudate nuclei) were heavily stained; others (for example, the magnocellular division of the red nucleus) were practically unstained, whereas many (for example, the supraoptic nucleus and lateral thalamic nuclei) showed intermediate grades of staining. As a possible explanation for these observations, it was proposed a few years ago that the terms 'cholinergic' and 'adrenergic' might define the predominant, but not necessarily the exclusive, transmitting agent of a given neurone, and that those containing intermediate concentrations of acetylcholinesterase might liberate both acetylcholine and another transmitter[5].

Superior Cervical Ganglion

From the comparative effects of lipid-soluble and insoluble anticholinesterase agents, it has been shown that the neuronal acetylcholinesterase is separated by the cell membrane into external and internal fractions[8,9] and that transmission in the cat superior cervical ganglion is affected by inhibition of only the former[10]. At that site, the external, or functional, acetylcholinesterase is entirely presynaptic[11], in contrast to the neuromuscular junction, where most of the enzyme is postsynaptic[12]. From this it was inferred that acetylcholinesterase serves different primary functions at the two sites. In the course of an investigation of the physiological function of acetylcholinesterase in the ganglion, my colleague, Volle[13], determined the mean threshold doses of intra-arterially injected carbamylcholine and acetylcholine for producing postganglionic activation in series of normal and preganglionically denervated cats, both before and after inactivation of the ganglionic acetylcholinesterase by di*iso*propylfluorophosphate. To our surprise, the thresholds to both agents were markedly elevated by denervation; with carbamylcholine, a nearly thirty-fold elevation was evident prior to administration of di*iso*propylfluorophosphate, whereas a five-fold elevation in the acetylcholine-threshold was unmasked only after inactivation of acetylcholinesterase. To explain these findings, we proposed that the threshold dose of acetylcholine or carbamylcholine in normal cats activated only the presynaptic terminals, causing them in turn to liberate acetylcholine immediately adjacent to the postsynaptic receptor sites, which in turn activated the ganglion cells. Following denervation, the higher thresholds were presumed to reflect those required for direct excitation of the ganglion cells. Consequently, it would appear that the primary function of the presynaptic ganglionic acetylcholinesterase is to limit the effect on the presynaptic terminals themselves of acetylcholine liberated there during transmission or the resting stage. Other investigators have published evidence of the susceptibility of the preganglionic terminals to activation by acetylcholine in pseudorabies-infected rats[14,15], and in normal cats[16], although the interpretation of the latter findings has been questioned[17].

Hypothalamico-Neurohypophyseal Tract

The work of Scharrer and Scharrer[18] and others has provided strong evidence that the hormones of the neurohypophysis are formed in the supraoptic and paraventricular nuclei of the hypothalamus, transported within their axons through the infundibulum, and stored until liberated in their terminations, the Herring bodies, within the neurohypophysis. From the work of Pickford and her associates[19,20], it appears likely that the hypothalamic control of neurohypophyseal secretion is regulated by cholinergic fibres. In an attempt to localize the cholinergic pathways involved, Abrahams[21], while visiting my laboratory, conducted a histochemical survey of the distribution of acetylcholinesterase in the hypothalamus of the dog. Unexpectedly, the enzyme was found in moderate concentrations only in the neurones of the supraoptic and paraventricular nuclei and their axons, and not in any of the presynaptic fibres adjacent to them. From the evidence cited earlier, this indicated that the only cholinergic neurones in the area of the hypothalamico-hypophyseal tract are the same ones which are assumed to elaborate the neurohypophyseal secretions. Among the suggestions offered at that time was that the same neurones might, indeed, liberate at their terminals both acetylcholine and the endocrine secretions, the latter under the influence of the former. More direct evidence of this possibility, and independent arrival at the same proposal, has recently been published from the laboratory of De Robertis. From an electron microscopic study of the neurohypophysis of the toad, these investigators discovered the presence in the neuronal terminals of two distinct populations of vesicles. Those of one group were dense to electrons, had an average diameter of 1150 Å., and could be traced back to the hypothalamus; they were identified as the neurosecretory product. Those of the other group were considerably less dense, averaged 420 Å. in diameter, and appeared only at the terminals; they were considered to be identical with the synaptic vesicles that have been described at various presynaptic sites[23], and may represent the storage form of acetylcholine and other transmitters[24]. Following this report, we have examined the neurohypophysis of the cat histochemically, and have found that the nerve fibres and associated Herring bodies stain consistently for acetylcholinesterase (Koelle, G. B., and Geesey, C., unpublished work). While indirect, the evidence is thus strong that the hypothalamico-neurohypophyseal fibres liberate both acetylcholine and endocrine secretions, and that the latter are under cholinergic control. In this situation, there is no participation of an immediate postsynaptic site.

Afferent Vagus

The primary sensory fibres are the only component of the peripheral nervous system for which a transmitter has not been identified. On the basis of their low contents of acetylcholine and choline acetylase, and the inconclusive effects of anti-cholinesterase agents on transmission[25], they are generally considered non-cholinergic. Matsumura, in my laboratory (unpublished work), has recently repeated the procedure developed by De Castro[26] for the establishment of functional re-innervation of the preganglionically denervated superior cervical ganglion by the afferent neurones of the peripheral vagus located in the nodose ganglion. Histochemically, the regenerated vagal fibres which synapsed with the superior cervical ganglion cells showed definite acetylcholinesterase activity, but were stained much less intensively than the normal preganglionic fibres. Ganglionic transmission was potentiated by eserine. It was blocked by hexamethonium and tetraethylammonium, in the same dosage-range as produced blockading of intra-arterially injected acetylcholine; however, much higher doses were required to produce equivalent blockade in normal ganglia. While alternative explanations are equally likely, these findings are compatible with the proposal that acetylcholine normally takes an intermediate or subsidiary role in liberating another primary transmitter of the afferent vagal fibres.

Postganglionic Adrenergic Fibres

During the past few years, Burn and Rand[27-29] have developed an interesting new concept of the mechanism of action of tyramine, ephedrine and related non-catechol sympathomimetic amines. Stated in brief, they have obtained evidence that the major component of the action of such amines consists in the liberation of endogenous catecholamines from storage sites in the vicinity of the peripheral terminations of the postganglionic adrenergic fibres. Furthermore, they have shown that a cholinergic mechanism probably is involved in the liberation of catecholamines by the adrenergic fibres following their stimulation. Evidence for the latter phenomenon is based on two types of findings: following atropinization, the injection of acetylcholine or nicotine produces sympathomimetic effects at peripheral sites; after depletion of the peripheral stores of catecholamines by pretreatment with reserpine, stimulation of sympathetic nerves to many organs produces cholinomimetic effects. The location of the peripheral stores of catecholamines is still conjectural. Burn and Rand have considered both the terminations of the adrenergic fibres themselves and adjacent chromaffin cells as possibilities. Without excluding the likelihood of the latter, the former is consistent with the present proposal; it is strengthened by the finding of Burn and Rand that the stores are depleted of catecholamines following sectioning and degeneration of the sympathetic fibres. Again recognizing the possibility of alternative interpretations, this might then represent another example of the release of acetylcholine from axonal terminals in response to the nerve impulse, and its triggering in turn the subsequent release of the actual neuroeffector transmitter, norepinephrine, from the same terminals. It is interesting to speculate that this process may occur in the sympathetic neurones containing moderate concentrations of acetylcholinesterase, whereas the release of norepinephrine from those practically devoid of the enzyme may occur normally without the mediation of a cholinergic mechanism. Most of these points have been discussed by Burn and Rand[29].

Peripheral Terminals of Motor and Sensory Fibres

The terminations of somatic motor nerves have been shown to respond to injections of various cholinomimetic drugs by the discharge of antidromically conducted impulses, simultaneously with postsynaptic activation of the motor end-plate[30,31]. This might be construed as reflecting a physiological situation similar to that proposed for the superior cervical ganglion; that is, that normally the acetylcholine first liberated by the terminals promotes the liberation of additional acetylcholine from the same source to act as the transmitter of the neuroeffector.

More provocative is the question of the possible role of acetylcholine or a similar agent at the peripheral terminals of sensory fibres. It is well established that a great variety of sensory terminals or end-organs (for example, carotid chemo-receptors and stretch receptors, Pacinian corpuscles, taste buds) are activated by injected acetylcholine, and that this action is blocked by ganglionic blocking agents such as hexamethonium, tetraethylammonium, and nicotine[32]. However, it is a moot point whether this reflects the participation of acetylcholine in their physiological activation by normal stimuli[33], or whether it represents a purely pharmacological phenomenon[34].

Yet there is a remarkable parallelism between the events which occur at the dendritic terminals of crustacean stretch receptors[35], or at the Pacinian corpuscle[36], and those recorded at the motor end-plate in response to stimulation of the motor nerve fibre or local application of acetylcholine[37]. The initial response to pressure at the tip of the afferent fibre within the bulb of the Pacinian corpuscle is the development of a transducer or generator potential; this, like the end-plate potential at the neuromuscular junction, is relatively slow, graded, and is not propagated. At the region of the first node of Ranvier, the transducer potential triggers the propagated nerve action potential, just as the end-plate potential initiates the propagated muscle action potential. Hence, the transducer potential of the Pacinian corpuscle has the characteristics of a localized, chemically induced response. In their electron microscopic study of the corpuscle, Pease and Quilliam[38] noted that the enclosed nerve terminal contains inclusions similar to the synaptic vesicles found elsewhere at presynaptic sites. The sum of these observations leads to the suggestion that the normal mechanism for the initiation of the transducer potential, in response to pressure, may be the liberation of free acetylcholine or a similar agent by the same terminal on which it then acts. The nerve filament and central core of the Pacinian corpuscle of the cat have been shown histochemically to contain both acetylcholinesterase and non-specific or pseudocholinesterase[39], although the latter undoubtedly predominates[40,41]. A similar ratio for the two enzymes has been noted in the carotid body of the cat, in which the chemoreceptor cells contain considerable pseudocholinesterase and the nerve fibres a low concentration of acetylcholinesterase[4]. As in the terminals of the hypothalamico-neurohypophyseal tract, the Pacinian corpuscle represents a possible site of acetylcholine function where apparently no actual postsynaptic site is involved.

Conclusions

In the foregoing discussion, evidence from several lines of investigation has been presented in support of the proposal that acetylcholine, released at the presynaptic terminals by a nerve impulse, may have a dual role in synaptic and neuro-effector transmission: an action at the same site effecting the release of another transmitter, or possibly of additional quanta of acetylcholine, and a transmitter action at the postsynaptic site. This does not necessarily imply that acetylcholine plays any direct part in the propagation of the conducted nerve

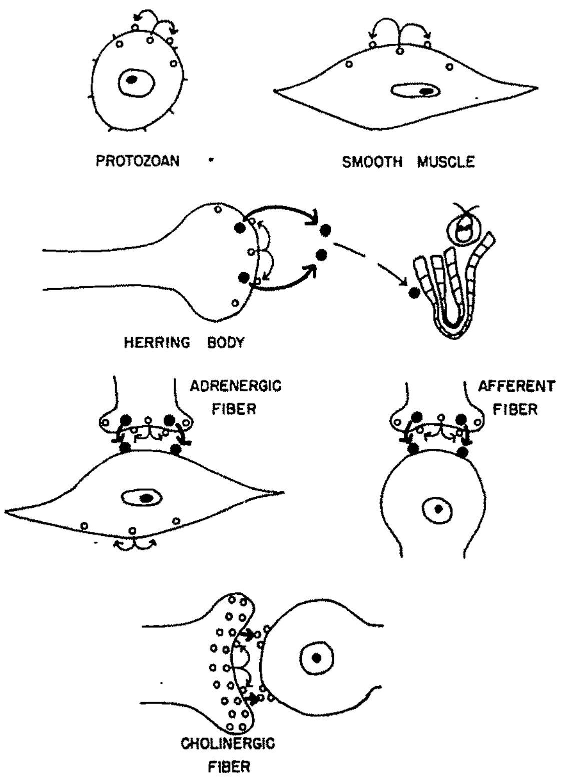

Fig. 1. Diagrammatic representation of the (1) direct influences of acetylcholine localized to its sites of liberation (protozoans, smooth muscle), (2) indirect influences through liberation of hormones acting at remote sites (from Herring bodies) and of neurohumoral agents acting at adjacent sites (from adrenergic and primary afferent fibres), and (3) direct influences at adjacent sites as a neurohumoral transmitter (from cholinergic fibres)

impulse, as proposed by Nachmansohn[42], nor does it preclude consideration of that possibility. The two actions considered here are presumably localized.

The postsynaptic transmitter role of acetylcholine seems now too well documented to require further discussion. There is also considerable evidence for its action at sites of release where no process of intercellular transmission is involved. The most direct demonstration of this phenomenon is in the ciliated protozoon, *Tetrahymena gelii*, which contains acetylcholinesterase, and in which acetylcholine appears to exert some control over ciliary activity[43]. Higher in the evolutionary scale, acetylcholine is involved in the beat of the cilia in the gills of the clam, *Mytilus edulis*; here, it is apparently formed by, and acts on, the ciliary epithelium without the intervention of any neural mechanism[44]. Likewise, in mammalian smooth[45] and cardiac[46,47] muscle, acetylcholine probably has a role as a 'local hormone', in that it appears to be liberated by the same muscle fibres on which it acts in the regulation of tone and rhythmicity, perhaps through modification of membrane permeability; superimposed on this inherent mechanism is the influence of acetylcholine liberated from the postganglionic parasympathetic fibres.

The proposed physiological activity of acetylcholine may be summarized in Fig. 1. At some sites, it has only a localized action on the cells in which it is formed, as in the last-quoted examples. Among such localized effects are included the liberation of secretory substances acting at a distance, as in the neurohypophysis, and, in the nervous system, of neurohumoral agents such as norepinephrine in adrenergic fibres, and perhaps an unidentified transmitter in the primary afferent fibres. In the so-called cholinergic fibres, sufficient acetylcholine is liberated, quite possibly in two steps, to act both locally, as above, and as the transmitting agent at the postsynaptic site. A universal role of acetylcholine at all synaptic and neuroeffector sites is not necessarily implied. In some cases, another agent or agents may have similar functions at the presynaptic site, just as other neurohumoral transmitters act post-synaptically where so-called non-cholinergic fibres are involved. Furthermore, the possibility is not excluded that a given fibre might liberate more than one transmitter acting post-synaptically, as previously proposed[5]. Finally, in isolated instances, synaptic transmission may occur without the mediation of a neurohumoral agent[48].

THE GASSIOT COMMITTEE OF THE ROYAL SOCIETY AND METEOROLOGICAL RESEARCH

By DR. D. C. MARTIN, C.B.E.

Assistant Secretary of the Royal Society

IN 1871, Mr. John Peter Gassiot conveyed to the Royal Society £10,000 of Italian Irrigation Bonds for the purpose of assisting magnetical and meteorological observations with self-recording instruments, primarily in the Kew Observatory. The Society set up its Gassiot Committee in the same year, and, apart from the Society's Sectional Committees, its Finance, Library and Scientific Relief Committee, it is one of the oldest of the Society's committees. The income of the Gassiot Fund has since 1871 been applied to the purposes set out in the Gassiot Trust Deed. Until 1910 the proceeds were passed first to the Kew Committee, then to the National Physical Laboratory Account of the Royal Society when the National Physical Laboratory had responsibilities in respect of the Kew Observatory. In 1910 the management of Kew Observatory was transferred to the Director of the Meteorological Office, with provision for scientific advice from the Gassiot Committee. Since 1920, when the Meteorological Office was incorporated into the Air Ministry, the income of the Gassiot Fund of the Royal Society has been paid annually to the Air Ministry on the recommendation of the Gassiot Committee in accordance with John Peter Gassiot's wishes.

In 1942, after consultation with the Air Ministry, it was agreed that the Royal Society should cooperate with the Meteorological Research Committee to assist the Air Council in the development of meteorological research on a wider basis and the Gassiot Committee was given terms of reference which included the following: (1) to advise the Royal Society on matters relating to pure research in meteorology and to supervise the disposal of such funds as may be made available by Council for this purpose; (2) to recommend as to the work of the meteorological and magnetic observatories with which the Society is connected; (3) to administer the Gassiot and other trust funds applicable to their maintenance. The Council of the Society asked the Committee to formulate plans for work on atmospheric composition, photochemistry, ultra-violet spectroscopy, synoptic meteorology and infra-red spectrometry. The Committee set up three sub-committees to assist it in encouraging this new programme of work, the sub-committees being entitled: (*a*) Atmospheric Composition and Motion; (*b*) Photochemistry of the Atmosphere; (*c*) Atmospheric Radiation and Temperature. With the aid of a grant, which was initially £5,000 per annum, and was later increased to £7,000 per annum, a worthwhile programme of work has been undertaken at a number of university centres. Among these were pioneering ozone studies by Prof. G. M. B. Dobson, at the University of Oxford, which have led to the creation of the permanent ozone survey service of the International Ozone Commission of the World Meteorological Organization; ultra-violet spectroscopic studies by Dr. T. W. Wormwell at Cambridge; infra-red work by Prof. P. A. Sheppard at the Imperial College of Science and Technology; research on molecular spectra by Dr. R. W. B. Pearse at the Imperial College; excitation of spectra by Sir Harrie Massey at University College, London; measurement of absorption cross-section by Prof. R. W. Ditchburn at the University of Reading; studies of airglow and auroral phenomena by Prof. D. R. Bates at the Queen's University of Belfast, and by Mr. J. Paton at the University of Edinburgh; and study of atmospheric winds by Mr. J. A. Ratcliffe at the Cavendish Laboratory, Cambridge. These studies have been carried out in close co-operation with various programmes of the Meteorological Office and Prof. T. G. Cowling of the University of Leeds, as well as Prof. D. R. Bates and others, contribute to the theoretical aspects of the work. Annually, the Gassiot Committee presents a report on its work to the Royal Society Council, and this report is forwarded to the Secretary of State for Air. From time to time, on the recommendation of the Gassiot Committee, special Royal Society discussion meetings have been held on subjects in the Gassiot programme. Prof. G. M. B. Dobson was the Committee's chairman during 1942–47, when he was succeeded by Sir David Brunt. Since 1952, Sir Harrie Massey has been chairman.

As early as 1953 the Gassiot Committee set up a small *ad hoc* sub-committee to consider whether atmospheric research, using rockets, might be initiated in Great Britain, and it organized a conference on the subject which was held in Oxford in that year. In 1955 a grant of £50,000 was received by the Royal Society from the Air Ministry for a programme of investigation of the upper atmosphere using high-altitude rockets. The Gassiot Committee created a new sub-committee to co-ordinate work at a number of university centres and to co-operate with the Ministry of Supply, particularly the Royal Aircraft Establishment. This programme, using *Skylark* rockets, has been very successful and has now been incorporated into the larger United Kingdom Space Research Programme which owes its beginning to the initiative taken by the Gassiot Committee in 1953.

During the past few years the organization of research programmes under the ægis of the Meteorological Research Committee has been re-organized, and some of the work hitherto conducted by the Gassiot Committee is considered to be more appropriately carried out directly by the Meteorological Research Committee itself through extra-mural contracts with university scientists. Some of those who have been supported in the past through the Royal Society will continue on the basis of such contracts and others wishing to carry out meteorological research should make application to the Director-General of the Meteorological Office, who is willing to support such research at university centres.

The Meteorological Office is, however, also anxious to continue its long and intimate connexion with the Gassiot Committee, and the Office recognizes that it provides an excellent medium for encouraging a wider interest in the problems of the atmosphere in universities, not least in subjects which border on meteorology. Arrangements have therefore been made for continued co-operation with the Meteorological Research Committee, it being agreed that the Gassiot Committee will concentrate its efforts on those problems of the physics of the atmosphere and allied subjects that are not at present dealt with by the Meteorological Research Committee. Initially, the Gassiot Committee, supported by an Air Ministry grant, will encourage further research in the photochemistry of the atmosphere and will promote, through discussion and other means, interest in other aspects. Close co-operation will be maintained with the Meteorological Research Committee by arranging joint meetings to discuss the Gassiot research programme. It is hoped that university physicists and others interested in its programme and not already in contact with the Gassiot Committee will approach the Royal Society.

The time-honoured association between the Meteorological Office and the Gassiot Fund, instituted in 1871, is to take a new form, which is warmly welcomed by the Royal Society. The Secretary of State for Air has approved the recommendation of the Meteorological Committee that two wholetime fellowships for research in the fields of seismology and geomagnetism respectively be established.

The income of the Gassiot Fund, now paid annually to the Air Ministry as mentioned above, will be regarded as a contribution to one of the fellowships, which will be tenable at Kew Observatory, and both fellowships are to be known as Gassiot fellowships, thereby preserving the historic connexion with John Peter Gassiot. The Royal Society Council accepted the invitation to nominate two representatives to the selection committee for these appointments, and Sir Edward Bullard and Sir Basil Schonland agreed to serve.

This story, which began ninety years ago, is an example of how a relatively small gift placed in the hands of a responsible body by a benefactor of science to encourage scientific endeavour has led to the development of a significant programme of co-operative research on a scale beyond his wildest dreams.

CARL LUDWIG GIESECKE (1761–1833)

By JOAN M. EYLES

SIR CHARLES GIESECKE, best known as a mineralogist, was born in Augsberg on April 6, 1761. His real name was Johann Georg Metzler, and his reasons for changing his name have never been satisfactorily established. He studied at Göttingen under J. F. Blumenbach, from whom he received his grounding in mineralogy. In his early years he was devoted to music and the stage, associating with Mozart, and taking some part in writing "The Magic Flute". This period of his life, perhaps some thirteen years, was mainly spent in Vienna. In 1794 he resumed his mineralogical studies, and travelled extensively to collect minerals, first in Austria and Germany, later in the Scandinavian countries.

In 1805, Giesecke was in Copenhagen, and was then commissioned by King Christian of Denmark to journey to Greenland to examine its minerals and prepare maps. He arrived in Greenland in 1806 and spent nearly seven years there. His private collection of minerals, which he had left in Copenhagen, was destroyed when the English navy bombarded the city in 1807. While in Greenland he discovered the famous cryolite occurrence at Ivigtut, on the Arsuk Fiord. Specimens of this rare mineral, a double fluoride of sodium and aluminium, had been sent to Denmark in the eighteenth century by missionaries, but the place from which they had been obtained was not known until Giesecke located it. This deposit later became of great importance to the aluminium industry. On his return to Denmark in 1813, Giesecke's ship called at Leith, and he spent some time in Edinburgh with Scottish mineralogists. Here he found some of the minerals that he had collected in Greenland. The ship in which they had been dispatched to Denmark had been captured by a French privateer, which, in turn, had been captured by an English frigate.

While in Edinburgh, Giesecke learnt that the Royal Dublin Society wished to appoint a professor of mineralogy. He applied for the post, and was elected by a large majority over several other candidates, although at the time he did not know enough English to lecture in the language—an indication of the esteem in which his achievements as a mineralogist were held. Giesecke held this post in Dublin until his death. In 1816, he was made a knight of the Danish Order of the Dannebrog, and became known as Sir Charles Giesecke. Thenceforward, apart from a brief return to Denmark and his native Augsberg between 1817 and 1819, he made Dublin his home. Here he lectured on mineralogy, arranged the valuable collections of the Royal Dublin Society, and also made mineralogical journeys into the west of Ireland. His published work relates mainly to Greenland and Ireland. He died suddenly in 1833, and the museum of the Society was closed for a fortnight as a mark of respect for his memory. His portrait, by Raeburn, was presented to the Society in 1817.

OBITUARIES

Dr. C. V. Drysdale, C.B., O.B.E.

Charles Vickery Drysdale, well known for his work on the design of electrical measuring instruments, died at Bexhill on February 7, at the age of eighty-six.

He was born in 1874, his parents being Dr. Charles R. Drysdale and Alice Vickery Drysdale. Like his father, his mother also was medically trained and was well known as Dr. Alice Drysdale Vickery (retaining her maiden name Vickery for professional purposes). She was born at Barnstaple, Devon, in 1846 and was fully trained in medicine and surgery for six years in London and Paris, but even in 1880 the British examining bodies refused to accept women. She went to Dublin, however, and obtained diplomas at King and Queen's College of Physicians certifying her as physician and licentiate in medicine and midwifery.

Dr. Drysdale was educated privately, and at Finsbury Technical College, and the Central Technical College, South Kensington. He was associate head of the Electrical Engineering and Applied Physics Department of the Northampton Institute (London) during 1896–1910.

He became a fellow of the Physical Society in 1898, and was a member of Council 1936–39 and Duddell medallist in 1935. He was also a member of the old Optical Society, of which he became president for 1903–4. A founder fellow of the Institute of Physics in 1920, he served on the Board during 1924–25 and was a vice-president during 1932–36 and editor of the *Journal of Scientific Instruments* during 1927–28. He was a Fellow of the Royal Society of Edinburgh and a member of the Board of Managers of the Royal Institution (1934–36). In 1920 he delivered the Kelvin Lecture on "Modern Marine Problems" at the Institution of Electrical Engineers, of which he was a member. He was honorary secretary of the Students' Section of the Institution of Electrical Engineers in 1894. He was also a Fellow of the Royal Statistical Society.

In addition to his scientific activities, Dr. Drysdale was a staunch member of the Malthusian League, of which he had been secretary, president and editor of the League's *Journal* during 1907–16. In 1921 and 1925 he had acted as president of Neo-Malthusian International Conferences in London and New York. He was a member of the Athenæum Club.

He was well known for his work on optical instruments, and for many years (1902–29) was examiner to the Spectacle Makers' Company. Such a wide range of interests is seldom found in one individual.

During 1910–16 Dr. Drysdale was closely associated with Mr. H. Tinsley, during part of this period in partnership, as makers of electrical measuring instruments. There he supervised the manufacture of many of his inventions like the a.c. potentiometer and the polyphase wattmeter, which are still made to-day as high-precision instruments. One of his great achievements was the phase-shifting transformer, the basis of servo-mechanisms in use throughout the world.

I first met Dr. Drysdale in January 1918 when he joined the staff of the Admiralty Research Laboratory at Parkeston Quay, Harwich. There he applied his wide knowledge of alternating current theory and electrical instrument design to Service problems. He designed sensitive mechanically tuned a.c. relays of sub-audio frequency, which could be actuated at a considerable range by the electromagnetic field surrounding a cable, lying on the sea bed, carrying alternating current of the same frequency as that of the relay. Afterwards (1919–21), at the Admiralty Experimental Station at Shandon (Gareloch), he made use of this system in the development of a 'leader cable' with visual indication on the bridge, to show the navigating officer the position of his ship, port or starboard, relative to the cable. Certain anomalies in this otherwise simple and useful system were observed, however, and this led Dr. Drysdale to make a very thorough full-scale investigation of the field distribution below and above the sea-surface around a submarine cable carrying alternating current. This work was done in Gareloch (off the Clyde) near Shandon and Rhu. The results of this important investigation, combined with those of theoretical and model-scale experimental work by S. Butterworth at the Admiralty Research Laboratory, Teddington, were published in the *Philosophical Transactions of the Royal Society* in 1924. This provided an explanation of the ambiguous indications of Dr. Drysdale's experimental leader cable. During the course of this research be became the first superintendent of the Admiralty Research Laboratory, Teddington, in 1921, a post which he held until 1929. In that year he was appointed director of scientific research, Admiralty, in succession to Sir Frank E. Smith. While serving in this post, in which he was in charge of all Admiralty research establishments, he was made a C.B. in 1932. He retired from Admiralty service in 1934.

He was a prolific writer, having published many original scientific and electrical engineering papers in *The Journal of the Institution of Electrical Engineers, The Electrician, The Proceedings of the Physical Society, The Journal of Scientific Instruments*, etc., as well as many contributions on Malthusian and Neo-Malthusian principles. One of his most important scientific papers is the one to which I have referred (*Trans. Roy. Soc.*) above. His book on *The Foundations of Alternating Current Theory* (published in 1910) was based on a series of lectures, extending over five years, which he gave at the Northampton Institute. This was one of the earliest efforts of which I am aware to emphasize the close analogy which exists in the theory of electrical and mechanical oscillations. At the end of the First World War he contributed to a collected work on *Mechanical Properties of Fluids*, in which he dealt with submarine signalling and the transmission of sound through water. His best-known book, *Electrical Measuring Instruments* (two vols.), in collaboration with Mr. A. C. Jolley, contains the work of many years study, theoretical and experimental, of the principles of design and operation of all kinds of electrical measuring instruments.

Dr. Drysdale lived a very full and energetic life, having a wide range of interests. He always took a great delight in seeing his theoretical deductions verified by an experiment. I remember him, however, working on an experiment at the Royal Institution, after his retirement from the Admiralty, to demonstrate that the basis of Einstein's theory of relativity was wrong. At the time of his death he was busy writing another book.

In 1898 he married Bessie Ingram Edwards, who died some years ago. They had one daughter, Eva, who died young, and an adopted son, Eric, who is married and lives in South America.

A. B. Wood

Prof. A. H. Cox

The death of Prof. A. Hubert Cox on February 14, 1961, will be sadly mourned by his many students dispersed all over the world and by geologists in Britain and in Canada. After graduating at the University of Birmingham as a chemist, he studied in Strasbourg where he carried out research work on benzenoid compounds and a great variety of other chemical problems.

During the First World War he became engaged on chemical work of great national importance which ultimately caused him to turn from chemistry to mineralogy and finally to stratigraphic and structural geology. Even prior to becoming professor of geology in the University College of South Wales and Monmouthshire, he had carried out important research work on the Ordovician rocks of Wales. His enthusiasm and energy in tackling the difficult and unknown structure and petrology of Cader Idris became symbolic of his future interest in the geology of the Principality. His name will always be associated with the pioneering work that was done in the early part of this century on the older rocks of Wales and, in particular, with the establishment of type-sections in Pembrokeshire. Conscious of the contribution which geology and geologists should make to industry, he devoted himself to the problems connected with the development of the coals of South Wales. He was among the first to apply geophysical methods to the determination of geological structures, and his use of resistivity measurements in the Coal Measures became the basis for a great deal of the modern work in this field of geophysics. He was among the first to illustrate how resistivity methods could be used to locate water-saturated strata in the Coal Measures and how those could be used in the development of the mines. His earlier training as a chemist made him singularly able to conduct investigations into the incidence of silicosis, as it was then called, among the miners of the South Wales coalfield. So tireless were his efforts to secure knowledge of the environmental factors concerning this disease among miners and so conscious was he of his duty as a scientist to the community, that his work became responsible for the complete revision of the pensions schemes for miners afflicted with pneumoconiosis.

Likewise, his contribution to the welfare and the development of the University College, Cardiff, will always be remembered and revered, and very specially by the many students entrusted to his care. Through many of these he was able to make profound contributions to the understanding of the structure of the Canadian Rockies and more especially to that of the Selkirk Mountains. His arduous work helped to establish the location of several important reserves of gold and silver and he can be said to have been among the pioneers of the scientific development of the mineral resources of Western Canada.

W. D. Evans

NEWS and VIEWS

Director of the National Lending Library for Science and Technology: Dr. D. J. Urquhart

The Department of Scientific and Industrial Research recently announced that Dr. D. J. Urquhart has been appointed the first director of the National Lending Library for Science and Technology at Boston Spa, Yorks. Dr. Urquhart was educated at Barnard Castle School and the University of Sheffield where he graduated in 1931 with an honours degree in physics. Afterwards he obtained a Ph.D. in the Metallurgical Faculty at Sheffield, and then he worked in the research department of a steel works. In 1938, Dr. Urquhart was appointed to the staff of the Science Museum Library. During the War he was at the Ministry of Supply, engaged mainly in the technical administration of armaments inspection. In 1948, he was transferred to the Information and Intelligence Division of the Department of Scientific and Industrial Research, where he was responsible for the reorganization of the Headquarters Library and Records and carried out a number of surveys of the use made of technical literature in different industrial centres. In November 1956 he became responsible for planning the National Lending Library. Since then he has been wholly concerned with the planning and creation of the new library, which has included the introduction of Britain's Russian translating programme in co-operation with the National Science Foundation's programme in the United States. Dr. Urquhart writes frequently on library and technical information topics. In recent years he has made a number of notable contributions in this field, starting with a paper he read to the University and Research Section of the Library Association in January 1957 on the new National Lending Library. It was in this paper that Dr. Urquhart estimated the size and requirements of the National Lending Library, and forecast the huge growth of Chinese scientific literature in the future. He dealt with this subject again in a paper to the Library Association last year. In 1958, at the International Conference on Scientific Information in Washington, he reported the results of an interesting analysis of the pattern of borrowing from the Science Museum Library which has served to guide the acquisition policy of the National Lending Library.

Civil Engineering at Swansea: Prof. O. C. Zienkiewicz

Dr. O. C. Zienkiewicz, who has been appointed to succeed Prof. B. G. Neal (see *Nature*, 188, 896; 1960) in the chair of civil engineering at the University College of Swansea, will bring to his new appointment experience of both British and American universities.

After graduating from the Imperial College of Science and Technology in 1943, Dr. Zienkiewicz conducted research into some problems of gravity dam design under Profs. A. J. S. Pippard and R. V. Southwell at the same institution. In 1945 he joined Sir William Halcrow and Partners, and for four years he gained experience in the design and construction of dams and hydro-electric projects. He was then appointed a lecturer in civil engineering at the University of Edinburgh where he remained until 1957, when he joined the staff at Northwestern University, Evanston, as an associate professor, becoming a full professor in 1960. Dr. Zienkiewicz's research interests have ranged widely, embracing both fluid mechanics and stress analysis. Apart from his work on gravity dams, several of his early papers were concerned with the behaviour of surge waves and with problems of hydrodynamic lubrication. His main interest at present is in the field of thermal stress analysis in elastic and viscous materials, and he is investigating applications to the design of concrete dams, reactor shields and other shell structures. Several lines of approach are being considered, notably structural models and analogue methods as well as analytical and numerical procedures. The building of new accommodation for all the Departments of Applied Science is to commence at Swansea in 1962. Dr. Zienkiewicz will therefore have the opportunity to plan further developments in civil engineering, specially suited to his own research interests, and he must also establish arrangements for teaching the much greater number of undergraduates to be admitted in the near future. His colleagues in this task will be Prof. R. H. Macmillan (Mechanical Engineering) and Prof. W. Fishwick (Electrical Engineering), now chairman of the Department.

Zoology at Ghana : Prof. E. E. Edwards

Prof. E. E. Edwards, who retired this year from the chair of zoology at the University College of Ghana, has become director of a new Entomological and Parasitological Research Unit under the National Research Council established by the Ghana Government in 1958. He will therefore be able to continue his interests in tropical entomology and parasitology which were a feature of the University Zoology Department under his professorship. He was appointed to Achimota, then the University College of the Gold Coast, in 1952, and during his occupancy of the chair was responsible for the planning of the zoological laboratories at the new Legon site of the College.

Prof. R. D. Purchon

Prof. R. D. Purchon, who has now been appointed to succeed Prof. Edwards, goes to Ghana from the chair of zoology at the University of Malaya in Singapore, which he has held for eleven years. During that time he established a very active school for the study of the animal ecology of Malaya, with particular emphasis on marine biology. Facilities for this type of work are already well founded in Ghana, where Accra has served as a centre for much of the previous work of the University College in this field.

British Participation in Space Research

In asking leave of the House of Commons on March 21 to introduce a Bill to provide for the establishment of a Minister of Space Research and Development, and for connected purposes, Mr. Woodrow Wyatt argued that no real progress in this important new field would be made until Britain had a Minister in the Cabinet responsible for co-ordinating everything to do with space. The Americans were spending £3 10*s.* a year per head of their population on space development, and the Russians an equivalent sum because they knew that the resultant advances in technology would be injected into other branches of industry. Britain, however, was spending not more than 1*d.* per head, and to fall 3 or 4 years behind in any department gravely handicapped technologists and made their task of keeping Britain in the forefront more difficult. Mr. Wyatt asserted that too many Ministries had a fringe interest and none an overriding concern in space matters, and that the Minister for Science was not sufficiently interested. He referred to the profit to be made out of communication satellite systems, but alleged that effort was being duplicated and that the Postmaster-General was indifferent to the work being done in this field by firms like the English Electric Co., Hawker-Siddeley, and Pye, and maintained that the future of Britain's export trade and her standard of living depended on not being left out of the space age. Leave to introduce the Bill was granted and the Second Reading ordered for May 5.

British Funds for Oceanographic and Hydrographic Research

At the Committee stage of the Navy Estimates 1961–62 in the House of Commons on March 14, several questions were raised on the vote of £21 million for scientific services, an increase of £1·7 million. This represents about 5 per cent of the Navy Vote of £400 million, but Mr. C. Ian Orr-Ewing, Civil Lord of the Admiralty, admitted that the true expenditure on research and development was considerably more, including expenditure incurred through the Ministry of Aviation. The 98-in. Isaac Newton telescope now being erected at Herstmonceux would cost about £780,000, of which half would come from Navy Votes and half from the Treasury, and it would not only be used by the Royal Greenwich Observatory, but would also be available for general use by other astronomers in the United Kingdom. Replying to specific questions about hydrographic work, Mr. Orr-Ewing said that R.R.S. *Discovery II* would cost some £570,000 this year, of which £285,000 would come from the Navy Vote and £285,000 from the Development Fund. Its maximum range would be 15,000 miles and its cruising speed would be 9–10 knots. It would be 260 ft. long with a loaded draught of 18 ft., and it was planned to have a scientific plotting room at deck-level; electronic hydrographic, biological, chemical and general laboratories, a low-temperature laboratory and an underwater instrument room with a trunk leading through the bottom of the ship. About the same amount as last year would be spent on research and development of nuclear propulsion, but there was a considerable increase in salaries, wages and allowances, resulting from adjustments to keep those of the scientific staff with salaries of scientists in industry and elsewhere. The vote included a grant-in-aid to the National Institute of Oceanography and a subscription to the International Hydrographic Bureau.

Water Research in Britain

In a written answer to a question in the House of Commons on March 20 regarding Department of Scientific and Industrial Research grants for research on the utilization and conservation of water supplies, the Parliamentary Secretary for Science, Mr. D. Freeth, said that direct expenditure in such research could not be separated precisely from that which had an indirect bearing on the subject. The best estimates of current expenditure (1960–61) by the Department and co-operative research associations were: Geological Survey and Museum, £32,350; Hydraulics Research Station, £93,100; Water Pollution Research Laboratory, £148,650; British Coke Research Association, £18,750; British Leather Manufacturers Research Association, £6,800; British Paper and Board Industries Research Association, £9,500; Water Research Association, £35,000; current grants to universities for special research work, £11,000.

Students Awards in Scotland

In a written answer in the House of Commons on March 28, the Secretary of State for Scotland, Mr. J. S. Maclay, said that, with the agreement of the local authority associations, from next October awards would be made by the Scottish Education Department to full-time university students, students training as teachers and students taking advanced full-time or sandwich courses at other establishments. Although the education authorities would no longer make the awards, their local officers would assist the Department by interviewing students and making local inquiries when questions of special difficulty arose, and they would be responsible for advising young people in their area as to facilities available for further education. They would continue to award bursaries to other further education students and to school pupils. There will be standard maintenance allowances for students to whom the Scottish Education Department made awards at the rate fixed for the university or college which the student actually attended. These rates have been fixed on an interim basis as announced on December 19, and it is intended to undertake a comprehensive review of the rates during the coming year.

The Match-making Industry in Britain

To mark their hundredth anniversary, the well-known match-making firm of Bryant and May has issued an attractive booklet which describes not only the history of the company but also changes in the way matches have been made over the years. Matches were invented in 1827 by an Englishman named John Walker, whose substances were: potassium chlorate, sulphide of antimony and gum arabic. A piece of fine sandpaper was included in each box. Herbert Spencer called this invention the greatest boon and blessing to come to mankind in the nineteenth century. Match-making materials have varied little since the time of the first British patent granted to Francis May in 1855. The head of the 'strike-anywhere' match contains chlorate of potash (to provide the oxygen) and sesquisulphide of phosphorus, while a safety-head match consists mainly of chlorate of potash and sulphur, providing flame when rubbed against the amorphous phosphorus on the side of the box. The materials in both heads are bound together by special Scottish glue. The sticks are treated with paraffin to help them burn and ammonium phosphate to prevent smouldering. A feature of the match industry is the curious way certain districts in Britain will buy certain types of matches—only the box is different—and no other.

U.S. Federal Expenditure on Science

In its ninth issue of *Federal Funds for Science*, the National Science Foundation analyses Federal expenditure on scientific research and development in the fiscal years 1959–61, during which period the total increased from 6,200 million dollars to 7,700 million dollars in 1960 and an estimated 8,200 million dollars in 1961; the corresponding obligations are 7,400, 8,600 and 8,500 million dollars, respectively, and of the last, about 10 per cent is for basic research (Surveys of Science Resources Series. Pp. iii+89. Washington, D.C.: Government Printing Office, 1960. 50 cents). As in 1960, some 90 per cent of the total is expected to be administered by the Department of Defense, the Atomic Energy Commission and the National Aeronautics and Space Administration. 44 per cent of Federal obligations for basic research in 1960 were allocated to educational institutions, 30 per cent to Federal agencies and 14 per cent to profit organizations. Obligations to the National Science Foundation increased by one-third in 1960 to 72 million dollars, and an increase to 84 million dollars is anticipated in 1961. Of obligations totalling about 1,900 million dollars for basic and applied research in 1960, the physical sciences, including mathematics and engineering, accounted for 56 per cent, the biological sciences for 27 per cent and the remaining 17 per cent went to the psychological, social and other sciences. Of this 'other sciences', about 85 per cent is accounted for by research into the space sciences administered by the National Aeronautics and Space Administration. Trends in expenditure and obligations over the period 1940–61 are also analysed in the report.

The Australian Scientist

It is a fair wind that finds among the farrago of scientific journals one that is devoted to science in its broadest fields. The tendency in the past has been for most countries to produce at some time or other a scientific showpiece, and it was logical that in time Australian scientists should wish to make their contribution. *The Australian Scientist*, a new journal (1, No. 1 (February 1961). Pp. 70. Subscription rates (1 year): Australia, Fiji, New Guinea, New Zealand £A4 4*s*. 0*d*.; Commonwealth countries (excluding the above) £Sterling £3 12*s*. 6*d*.; Non-Commonwealth countries £Sterling £4 5*s*. 0*d*. Liechhardt, Sydney: Tasman Productions, 9–23 Upward Street, 1961), does much more than just act as a showroom for Australian science, and represents a major contribution to the communication of science in general. As would be expected from the strong editorial board, consisting of Prof. A. A. Abbie, Prof. S. T. Butler, Dr. A. S. Fraser, Prof. R. J. W. Le Fevre, Prof. H. Messel, Sir Mark Oliphant, Prof. R. N. Robertson, Prof. R. H. Thorp and Sir Samuel Wadham, the first issue sets a very high standard of material and presentation. The pattern of the journal follows the traditional form of many of the world's established journals, but rather than just represent science it also acts as a spokesman; and it is planned that a section of letters to the editor will commence as soon as practicable.

PHYSICS DEPARTMENTAL LIBRARY

The first issue contains, besides the foreword by Dr. D. A. Cameron, Minister for Health and Minister in Charge, Commonwealth Scientific and Industrial Research Organization, a forthright article entitled "New Deal in Science Education", by Prof. H. Messel, and articles on mast cells, automatic computation, seashore life in Australia, genetics, civil engineering, cosmic radiation, plasma physics, the cyclotron, drugs and the heart, all by Australian authorities, and aimed at the greatest possible circle of readers. The outward appearance of the journal is most striking, and all articles are generously illustrated, and some even include a portrait of the author. While certain illustrations are much enhanced by colour, it does not seem that some warrant it (Figs. 4 and 5 on pp. 64–65), and their reduction to black and white would have, at least, done something towards lowering the cost of production and hence the price of the journal.

Birds killed by Poisonous Seed-Dressings

A REPORT, issued jointly by the British Trust for Ornithology and the Royal Society for the Protection of Birds, is presented in an *Intelligence Unit Bulletin* (No. 13, March 1961) issued by the Council for Nature, and provides firm evidence that many, if not most, of the large numbers of birds found dead in various parts of Britain in the spring of 1960 had been poisoned by consuming dressed corn either directly or by eating some other creature that had itself eaten the corn. The report lists 67 localities from Aberdeenshire to Kent in which dead birds were found; in 59 of these cases seed dressings are believed to have been the cause of death. Sufficient corpses were analysed to point to dieldrin as the seed dressing principally concerned. The most numerous birds reported dead were wood pigeons; there were almost as many pheasants, and smaller numbers of rooks, crows, chaffinches, partridges and blackbirds. Among insectivorous and predatory birds killed were two each of the tawny owl, buzzard and wren, and single specimens of the barn owl, lapwing and kestrel. A few mammals were also reported killed in the same way, among them three dogs, three cats, two hares and singletons of the fox, weasel and hedgehog. Fear is expressed that another great slaughter of birds is likely this spring, due to the heavy sowing programme which, as a result of the wet autumn and winter, farmers will have to undertake in the next few weeks. An appeal is made therefore to all naturalists to send information of any dead birds they may find to Peter Conder, Royal Society for the Protection of Birds, 25 Eccleston Square, London, S.W.1. The basic facts required are the date on which kills began, the numbers and species of birds and mammals involved, and the name of the seed dressing used nearby. One or two of the corpses of birds larger than pigeons, from each kill, would also be most useful for chemical analysis to determine the cause of death.

Nature Conservancy: New Appointments

LORD HURCOMB has been appointed chairman of the Nature Conservancy in succession to Mr. Arthur Bryce Duncan. Previously, Lord Hurcomb was chairman of the Committee for England, and is succeeded by Prof. A. R. Clapham. Lord Howick of Glendale has been appointed as a member of the Nature Conservancy. Sir Charles Connell, Prof. J. H. Burnett and Major S. F. Macdonald Lockhart have joined the Conservancy's Scottish Committee; the vacancies having arisen through the retirement of Prof. J. R. Matthews, Major D. C. Bowser and Mr. Michael Noble. Dr. A. M. Massee and Prof. D. L. Linton have replaced on the Committee for England Sir William Taylor and Dr. A. S. Watt, who have retired. On the Committee for Wales, Prof. P. F. Wareing and Mr. W. Vaughan Lewis fill the vacancies arising from the retirement of Prof. F. W. Rogers Brambell and Mrs. I. M. Vaughan.

The Textile Institute Scholarships

THREE scholarships are being offered by the Textile Institute: *The Textile Institute Scholarship*, which is a three years scholarship, total value £1,050, for the study of textile technology, and is open to young people who are, or have been, or intend to be, engaged in the cotton spinning or cotton weaving section of the textile industry in the United Kingdom; *The Peter Coats Scholarship*, which is for two or three years to the value of not more than £100 per annum, tenable at the textile department of any technical college in the British Isles, and is open to students who wish to take a course leading to a college diploma or other qualification in subjects connected with the cotton industry; *The Rowland Spencer Scholarship* is for training or research, to the value of £100 per annum, for persons already engaged in the textile industry and undertaking a part-time course at a recognized technical college. The closing date for applications for all scholarships is May 1, and application should be made to the General Secretary, Textile Institute, 10 Blackfriars Street, Manchester 3.

Gulbenkian Foundation Grants

THE trustees of the Calouste Gulbenkian Foundation of Lisbon have announced the grants, totalling about £550,000, made during the second half of 1960 (making a total of more than £1 million for the year). Of these, grants in the United Kingdom and British Commonwealth total about £70,000. Among the grants in aid of science are: £2,000 per annum for five years to the University of London Institute of Archæology (total £10,000) for the academic part of a postgraduate course in the care and restoration of ancient buildings; £2,000 for a gas liquefier for the Gulbenkian Radio-carbon Dating Laboratory, to the University College of Rhodesia and Nyasaland; £29,949 for cytological work at the Institute of Histology and Embryology, University of Lisbon; £3,750 to the Fondation Européenne pour les Echanges Internationaux to enable postgraduate science students to study in Portugal.

University News: Belfast

ADRIAN P. ROBERTS has been appointed senior lecturer in engineering mathematics. Mr. Roberts has been a lecturer in electrical engineering at the Imperial College of Science and Technology.

The College of Aeronautics, Cranfield

THE following appointments have been announced: *Lectureships*, E. R. Norster and J. H. Dunmore (aircraft propulsion); H. B. Gatland (electrical engineering); D. Hodgetts and G. H. Tidbury (automobile engineering). *Senior research fellowships*, Dr. G. T. Csanady (Department of Aerodynamics); Dr.

W. D. G. Bennett (Department of Materials). *Research fellowships*, D. Hyde (Department of Flight); A. Kaye (Department of Materials).

Leeds

THE following appointments to lectureships have been announced: Dr. J. F. Bowers (mathematics); Dr. A. Myers (physics); Mr. M. Wells (electronic computing).

London

DR. D. J. BOHM, Research Fellow in the University of Bristol, has been appointed to the University chair of theoretical physics tenable at Birkbeck College. The following titles have been conferred: that of reader in spectroscopy in the University of London, on Dr. Edna M. F. Roe in respect of her post at the Institute of Cancer Research: Royal Cancer Hospital, and that of reader in chemical pathology in the University of London, on Dr. I. D. P. Wootton, in respect of his post at the Postgraduate Medical School of London.

Mr. Desmond Curran, senior psychiatrist at St. George's Hospital, has been appointed to the University chair of psychiatry tenable at St. George's Hospital Medical School. Mr. D. J. Wiseman, assistant keeper at the British Museum, has been appointed to the University chair of Assyriology tenable at the School of Oriental and African Studies. Dr. C. Long, head of the Biochemistry Division at the Institute of Basic Medical Sciences, has been appointed to the University readership in biochemistry tenable at that Institute.

Announcements

ANY material that has to do with the life of Alan Gregg, late of the Rockefeller Foundation, will be welcomed by his biographer. This should be sent to Dr. Wilder Penfield, Montreal Neurological Institute, Montreal, Canada.

THE annual conference of the Museums Association will be held in Plymouth during June 19–23, under the presidency of Dr. D. B. Harden. Further information can be obtained from the Secretary, Museums Association, 33 Fitzroy Street, Fitzroy Square, London, W.1.

A CONFERENCE on "The Control of Noise" is to be held at the National Physical Laboratory during June 26–28. Admission is by personal invitation and anyone interested should write to the Director, National Physical Laboratory, Teddington, Middlesex, from whom further information can be obtained.

THE Italian Society of Chemotherapy is organizing a symposium at the beginning of June. Among the subjects to be considered are: new penicillins; antitumoural antibiotics; activity and use of nitrofurane derivatives; radioprotective drugs. Further information can be obtained from the Secretariat of the Italian Society of Chemotherapy, Via Andrea del Sarto 21, Milan.

THE Northern Branch of Aslib is organizing a residential conference at St. Mary's College, University of Durham during April 20–22. To be included in the programme are a number of papers: "The Battle of the Books"; "O. and M. in the Library"; "The Function of the Library in Research Projects"; "The New University Library in Newcastle upon Tyne"; "The National Lending Library at Thorp Arch". Further information can be obtained from Miss E. Boddy, c/o Edgar Allen and Co., Ltd., Imperial Steelworks, Sheffield, 9.

"AUTOMATION—Men and Money" is the title of the first British conference on the social and economic effects of automation to be organized by the British Conference on Automation and Computation. The conference is to be held at Harrogate during June 27–30. Further information can be obtained from Miss Elizabeth Ellett, British Institute of Management, 80 Fetter Lane, London, E.C.4.

THE four hundred and fifth meeting of the Biochemical Society will be held in the University of Birmingham during April 28–29, when there will be a colloquium on "Metabolic Pathways of Foreign Compounds". Further information can be obtained from Dr. W. J. Whelan, Lister Institute of Preventive Medicine, Chelsea Bridge Road, London, S.W.1.

THE eleventh meeting of holders of Nobel Prizes will be held in Lindau during June 26–30. Among those present who are to speak are: Prof. A. I. Virtanen (Helsinki); Prof. L. Ruzicka (Zurich); Sir Robert Robinson (London); Prof. P. Debye (Ithaca). Further information can be obtained from the Secretariat der Tagungen der Nobelpreisträger, Lindau, Bodensee, Postfach 11.

A MEETING of the Welsh Soils Discussion Group, to be held on May 3, will take the form of a full-day field meeting in the Aberystwyth hinterland. The theme of "Glaciation as Related to Soil Profile Development" will be continued by a field examination of (*a*) soil profiles revealed in forest roads in Dovey Forest and (*b*) cliff sections along the coast south of Aberystwyth towards Aberaeron. Particulars can be obtained from Mr. James A. Taylor, Department of Geography, Alexandra Road, Aberystwyth.

THE sixth Nuclear Congress, organized by the Comitato Nazionale per l'Energia Nucleare, is being held at the Palazzo dei Congressi, Rome, during June 13–18. Three symposia are being included in the programme: "The Thorium–Uranium Cycle"; "Nuclear Applications in Agriculture"; "Autoradiographic Techniques in Medical Science". A study day on "Conventional Engineering Problems in Nuclear Plants" is also being arranged. Further information can be obtained from Ufficio Stampa e Relazioni Pubbliche, CNEN, via Belisario 15, Rome.

AN informal discussion on the effects of ionizing radiations on organic and biological solids will be held at the Laboratoire de Chimie Physique, 11 Rue Pierre Curie, Paris V$^{\text{eme}}$, during July 3–4, under the joint auspices of the British Biophysical Society and the Société de Chimie Physique. Information and application forms can be obtained from one of the organizers, Prof. J. A. V. Butler, Chester Beatty Research Institute, Fulham Road, London, S.W.3: Dr. L. H. Gray, Mount Vernon Hospital, Northwood, Middlesex, England; or M. Magat, 11 Rue Pierre Curie, Paris V$^{\text{eme}}$, France.

THE name of T. Kobayashi (Japan) as one of the vice-presidents of the International Union of Geological Sciences has been omitted from a note appearing in a recent issue of *Nature* (April 8, p. 132).

PLANT VIRUS DISEASES

A GENERAL paper-reading meeting of the Association of Applied Biologists was held at the British Museum (Natural History), Cromwell Road, London, on February 10. Dr. C. Potter was in the chair. Although not advertised as a symposium it might well have been, for it had a coherent content of new and unpublished work on diseases caused by plant viruses in crops.

Several themes, apart from the obvious ones implicit in the titles, linked the different contributions. The first was the ubiquity of soil-transmitted viruses, some known and some suspected to be transmitted by nematodes. Another was seed-transmission which recurred in several contexts, and a third, carried or 'pick-a-back' viruses. These are viruses that cannot be transmitted alone by arthropods, but may be so in the presence of another virus that is transmissible by a vector.

All these aspects of transmission were mentioned in the first paper on "Some Celery Viruses", by Mr. M. Hollings (Glasshouse Research Institute). Among viruses isolated from celery crops was celery yellow vein, transmissible by grafting and by manual inoculation of infected sap, as well as through naturally infected soil. It reacts strongly to antisera prepared against a strain of tomato black ring virus, which is transmitted by seed, soil and probably nematodes. Cucumber mosaic and lucerne mosaic viruses were isolated from the field. A previously unrecorded virus, provisionally called celery yellow spot, could be transmitted from celery to celery only when cucumber mosaic was present ; cucumber mosaic alone did not cause the symptoms, and yellow spot alone was not transmissible. Another previously undescribed virus, celery yellow net, was transmitted by grafting or manual inoculation only during the winter months; no aphid or other vector was found.

Mrs. M. A. Watson (Rothamsted Experimental Station) described carrot motley dwarf virus which causes a disease of carrots known to growers as purple top. In an experiment, infection in July caused a loss of about one ton per acre of carrots for every additional 15 per cent of plants infected. The willow-carrot aphid, *Cavariella aegopodiae*, retained the virus for many days when adequately fed on infected plants. Motley dwarf may be a complex of two viruses, motley dwarf proper and red leaf. Motley dwarf proper was transmissible by aphids and by manual inoculation to *Nicotiana* spp. but not by aphids thereafter. Red leaf has not been transmitted by manual inoculation, and does not seem able to infect *Nicotiana* spp. Possibly its presence enables motley dwarf to be transmitted by aphids, and it may be transmitted by seed in an attenuated form. Motley dwarf virus was infective in saps extracted with phenol, but infectivity was completely destroyed by addition of ribonuclease to a final dilution of 0·01 mgm./l., 3 min. before inoculation, suggesting that infective material in phenol extracts is nucleic acid.

Dr. J. A. Tomlinson (National Vegetable Research Station) showed that lettuce crops can be kept reasonably free from damage by lettuce mosaic virus in the summer, by sowing seed containing less than 0·1 per cent of seed-infection. In winter, cucumber mosaic caused a disease resembling that caused by lettuce mosaic. Cucumber mosaic is not transmitted by seed so control measures based on seed hygiene were less successful in winter than in summer. An unidentified virus caused symptoms similar to those of arabis mosaic when inoculated to *Chenopodium* spp., but was symptomless in lettuce.

Dr. R. Markham (Agricultural Research Council Virus Research Unit) presented a joint paper with Dr. R. MacLeod on "A Persistent Aphid-transmitted Virus Disease of Tobacco". This virus, provisionally called tobacco yellow net, was not manually inoculable, but was transmitted by *Myzus persicae*, which could retain it for several days after a single adequate feeding on infected leaves. It resembled the 'vein-distorting' component of K. M. Smith's tobacco rosette complex of viruses, and, like 'vein-distorting' virus, was able to act as a carrier for the other component of the complex, mottle virus, which was otherwise not transmissible by aphids. Yellow net might be easier to handle biochemically than other aphid-transmitted persistent viruses which usually have less amenable hosts than tobacco. However, vein-distorting virus, which it resembles, has proved disappointing in this respect.

At the afternoon session emphasis was on soil-transmitted viruses. Some of these, for example arabis mosaic, have previously been known to be transmitted through infected soil, but nematodes have only recently been shown to be the vectors.

Mr. R. M. Lister (Scottish Horticultural Research Institute), in a joint paper with Dr. A. F. Murant, described seed-transmission of arabis mosaic, raspberry ringspot and tomato black ring viruses in a wide variety of hosts, including many weeds. These viruses are disseminated by distribution of vegetative material from nematode-infested sites, but dissemination of infected seed may spread them even more widely. However, such spread is limited by the susceptibility of the wild plants to virus and vectors, and the amount of seed that becomes infected. Infected weeds may have poor ability to survive in competition with healthy ones and in cultivation. Even if they survive, it may be in sites free from suitable nematodes. These factors probably reduce the chances of virus being spread by seed transmission.

Speakers in the discussion also thought that the three viruses are mainly spread by infected propagating material, but the importance of the discovery that they are transmitted by seed was stressed. Mr. Lister mentioned that the viruses were pollen-transmitted, and distribution by pollen may be more effective than by seed.

Dr. B. D. Harrison (Rothamsted Experimental Station) gave a joint paper with Dr. R. D. Winslow on arabis mosaic virus. It included one of the first accounts of the behaviour of a nematode-transmitted virus in relation to its vectors. The virus has previously been associated with important diseases of raspberry, strawberry and cherry, very recently with white clover, marrow and celery. The patchy distribution of diseased plants in crops coincides with that in the soil of *Xiphinema diversicaudatum*, the vector of arabis mosaic virus. Adult nematodes usually transmit better than larvæ, but both are infective after being kept without plants for several weeks. The virus remains viable a much shorter time *in vitro*, and must be in some way stabilized in the nematodes; possibly it multiplies in them. Galls that develop on roots of plants infested with *X. diversicaudatum* are caused by nematode feeding and not by virus infection. Evidence is accumulating that transmission of different nematode-transmitted viruses is specific to particular species of nematodes. Ecological studies showed that in some districts hedgerow plants are important hosts of arabis mosaic and of *X. diversicaudatum*, but in others the vectors, and probably the virus, are more widely distributed in the fields. An interesting discussion centred around the possibility that cultivation, and not preference of the nematodes for a particular environment, determined this distribution. A grass field that had not been cultivated for thirty years had nematodes only near its hedgerows, but Dr. F. Raw did not think thirty years to be a particularly long time for soil animals not to have returned after cultivation.

An important paper by Mr. R. Cropley (East Malling Research Station) described the identification and symptoms of viruses isolated from cherry trees with rasp leaf and leaf roll diseases which are widespread and damaging in sweet cherry orchards. Rasp leaf was found associated with raspberry ringspot virus, but the symptoms, of reduction in leaf size and rough enations on the backs of the leaves, can also be caused by arabis mosaic virus. Cherry leaf roll virus is readily transmissible by manual inoculation to many herbaceous hosts. Symptoms, thermal inactivation and particle size and shape are characteristic of soil, or nematode-borne 'ringspot' viruses, but leaf roll seems to be distinct from those already known. It is manually inoculable from cherry to *Prunus pennsylvanica*, and from tobacco to cherry and strawberry. Virus can be detected in young leaf tissues in the spring, but not in summer and autumn.

In the discussion Dr. Posnette emphasized the importance of cherry leaf roll ; he thought that degeneration of orchards often attributed to age or poor husbandry was really caused by the virus. It was suggested that Tomlinson's lettuce latent virus (see paper No. 2) might be the same as cherry leaf roll virus.

An interesting symposium can be made to sound dull by the use of the dread word 'practical'. However, this series of papers gave information of practical importance to farmers and growers, as is only proper for applied biologists, but also contributed to general understanding of plant virus problems and reported advances of a more fundamental kind in virus research. There was clear indication of trends that could become important in the future.

MARION A. WATSON

PHYSICAL CONDITIONS OF SOIL

On March 1 about eighty members of the National Vegetable Research Station Association attended talks and demonstrations on "Soil Physical Conditions affecting Plant Growth", given by the staff of the Chemistry and Irrigation Sections at Wellesbourne.

It is well known that the overall physical condition of a soil, often referred to as soil structure, and, in the surface layers, soil tilth, has considerable effect on the growth of plants. Furthermore, applications of bulky organic materials, such as farmyard manure and compost, have given yields of vegetables much higher than those produced by inorganic fertilizers alone. The general reason advanced for this difference is that the bulky organic manures improve the physical condition of the soil as well as providing plant nutrients. While many opinions have been expressed, in text-books and elsewhere, as to which of the soil physical properties are important, for example, water-holding capacity and aeration, there is still a dearth of experimental evidence on the relations between measurable specific physical properties of the soil and plant growth.

Experimental work in progress at Wellesbourne on the following subjects was described and demonstrated: soil aeration; soil moisture characteristics; the uptake of nutrients by plants, especially in the early seedling stage; the distribution and activity of the roots of crop plants; and the effect of soil physical conditions on the responses of plants to applications of irrigation water.

At present, there is no satisfactory method for measuring soil aeration, and hence there is no means of assessing the importance of this factor in crop production. The distribution of oxygen in a soil may affect plant growth by influencing the ability of plant roots to take up nutrients, and by altering the activities of the micro-organisms and thus the amount of nutrients available to the plant roots. Work, so far, has been confined to the latter topic. With the view of using the activities of the soil micro-organisms as indicators of availability of oxygen, the effect of oxygen concentration on them is being studied. Actively metabolizing micro-organisms in soil are covered with a thin layer of water which is exposed to the soil atmosphere. Since large differences exist between the oxygen concentrations at different points in the water layer, techniques have been devised which enabled the activities of the soil micro-organisms to be correlated with the oxygen concentration in the water at their surfaces. It has been shown that the respiration of the soil organisms and nitrification were not inhibited, and denitrification and anaerobic decomposition of soil organic matter were not induced, unless the concentration of oxygen at the microbial surfaces was less than about 10^{-6} M. Using microbial activities as indicators of oxygen concentration, physical theories of the distribution of oxygen in columns of moist soil crumbs are being tested, and efforts are being made to find out if it is possible to obtain the parameters necessary for the theories from simple measurements on field soils.

In field experiments at Wellesbourne during 1954–61, applications of farmyard manure produced large increases in the yield of a wide range of vegetables. Measurements of the moisture characteristics of the manured and of the unmanured soils during the growth of a crop of leeks showed that at planting time in July the available water capacity of the two soils was the same, but by October the available water capacity of the manured soil was 24 per cent greater than that of the unmanured soil. Further, the extra water was held at tensions less than 0·33 atmosphere, and, therefore, would be expected to be readily available to plants. These results could explain the large yield response of leeks to the application of farmyard manure which is especially marked in dry seasons.

The results of growth analyses of carrot crops grown with and without farmyard manure showed that, during the very early stages of growth, the rate of increase of dry weight was much greater on plots where farmyard manure had been applied, and that this initial difference could affect the final yield of the crops. Chemical analyses of the seedlings revealed differences in composition which were larger than might have been expected from the results of laboratory assessments of the available nutrients in the treated and untreated soils. Experiments on the uptake of nutrients by seedlings in the first five days after emergence have shown that the amount of potassium taken up during this period affects the rate of growth of the seedlings for about 35 days, irrespective of the potassium nutrient treatment given after the first 5-day period. While it appears that potassium was involved in the stimulation of growth of the seedlings on the farmyard manure-treated plots, the reason for the much greater uptake of potassium by seedlings on these plots is not known.

The effect of soil conditions on the distribution and activity of plant roots is important to the nutrient and water economy of the plant, but, unfortunately, there is little fundamental information on this subject. Some work has been done at Wellesbourne on the distribution of the root systems of various vegetable crops, and attention is now focused on devising suitable techniques for the investigation of the factors affecting root activities in defined soil systems.

In the midland, eastern and south-eastern counties of England, crop production is limited in four years out of five by insufficient rainfall. Irrigation is now widely practised in these areas and, in general, produces increased yields of most crops. However, the response to applications of irrigation water is affected by the physical condition of the soil, and on certain soils, notably silts and fine sands, yields can be decreased if irrigation water is applied in such a way that the surface of the soil is beaten down to form a 'cap'. Methods of irrigation to overcome this disadvantage are now being studied, together with the causes of the detrimental effect of the 'cap' on plant growth.

F. HAWORTH

SCIENCE AND EDUCATION IN COMMUNIST CHINA

IN a paper presented to the American Association for the Advancement of Science at its New York meeting on December 27, 1960, Dr. T. H. E. Chen, describing the position of science and scientists in Communist China, explains that to the Chinese Communist science and politics were inseparable, and every scientist had to pledge himself unreservedly and unquestioningly to the Communist party: the study of politics and ideology was as important as the study of science. Ever since 1949, increasing pressure had been exerted on China's scientists to conform politically and ideologically, and scientists were required to follow the direction of the Communist party in their scientific work. Political interference was found in many areas and the idea of objective science was rejected. As regards the present position, Dr. Chen said there was a new interest in science and technology, and technical institutes at secondary and higher levels were producing large numbers of engineers, technicians and technologists. Better facilities for scientific study had been provided since 1956–57, living conditions and salaries for scientists had been improved, and laboratory and library facilities expanded. The predominant emphasis remained on applied science and technology and also violent opposition to science for its own sake. Moreover, scientists were so hemmed in by political restrictions and burdened with political requirements that there was little room for initiative and creativity. There had, however, been a mushroom growth of new ideas in technical innovations and improvements, but despite such spectacular results, much was lacking from the point of view of a long-range and balanced programme of scientific development. There was reason to believe, however, that beneath the outward conformity a good deal of resistance to Communist pressure still existed among scientists.

In a paper on the training, growth and utilization of scientific and technical man-power in Communist China, presented at the same meeting, L. A. Orleans, of the Library of Congress, reviewed briefly the educational system in Communist China, and especially its capacity to produce scientists and technicians, and then considered the professional man-power of China, its competence and the effectiveness with which it is used. Mr. Orleans stressed the importance of using with discretion data on Communist China. Despite some revolutionary educational reforms, the framework of the educational system is approximately that which existed under the Nationalist regime, but it is supplemented by a great variety of educational facilities which do, in fact, provide training in various subjects and skills with different degrees of complexity and intensity. Between 1949 and 1957 enrolment in primary schools increased by 40 million, in secondary schools by about 6 million and in institutions of higher education by 300,000; during 1958 enrolment in primary schools increased from 64·3 million to 86 million; in secondary schools from 7 million to 10 million; and in universities and institutes from 440,000 to 660,000; but inevitably the already inadequate education received by most pupils deteriorated further. The most glaring weakness in higher education is probably over-specialization: there is virtually no possibility of interchange among specialists, and in most institutions physics, for example, is no longer taught as a distinct and integrated subject. Despite the limited facilities, teachers and funds, the system provides a large number of people with an appreciation for education, and a relatively small number with the knowledge necessary to lead the drive towards industrialization and world status.

Mr. Orleans accepts the figure of 625,000 as most closely reflecting the number of persons with higher education at present living in Communist China, more than half of whom are under thirty years of age and almost 80 per cent are men. During the past few years the number of professional workers has been growing at about 10 per cent per annum, and under the Communists the greatest increase has been in engineering, followed by education and agriculture. Of 170,000 with engineering degrees, 90 per cent have received them since 1949, while of 38,000 graduates in the natural sciences, two-thirds are Communist trained. Great inefficiency appears to exist in the estimates of future man-power requirements and in placing graduates. Most of the serious scientific work is being done in the Chinese Academy of Sciences, which in 1958 had almost 6,000 research workers (almost 75 per cent being assistants, trainees or technicians), and its affiliated institutes; even here scientific research was integrated with production. In 1958, the 650 research institutes in science and technology employed a staff of 82,100, of whom 18,100 were research and technical workers, 14,700 in industry and communications, 1,200 in agriculture and related fields and 2,200 in medical science and public health, but it cannot be assumed that all have completed professional training. Many engineering graduates are, in fact, little more than skilled technicians and many science graduates advanced laboratory technicians. China undoubedly possesses a limited number of first-rate scientists, but, at least in the immediate future, her achievements in science, as in overall economic growth, will depend on how much help is obtained from the U.S.S.R. More and more persons will graduate from the advanced institutions now established to train scientists and technologists, but their function must be problematic while China continues the policy of adapting present knowledge to immediate needs rather than sponsoring creative research.

TREATMENT OF RINGWORM BY GRISEOFULVIN

TINEA CAPITIS (ringworm of the scalp) is a dermatomycosis mainly affecting groups of children of school age. Although not serious, the disease is conspicuous, and affects the morale of children, keeping them from school and from participation in normal childhood activities. The bacterial complications to which it may give rise are sometimes serious.

The disease is carried home from school or from a group of playmates, and a reservoir of infection is then established among adults. In some communities in Israel, the proportion of adults suffering from ringworm is higher among women than among men. On the other hand, in Moslem communities it appears to be the men who maintain the disease and run the risk of serious infection, because of their custom of shaving their heads, which is frequently done without due attention to hygiene. Moslem women are protected by the care they give their hair.

Ringworm is particularly widespread in communities where life is organized around the family or the tribe or where people live together in crowded conditions. Some persons contract ringworm more easily than others exposed to the same risk, and the disease is more frequent among children suffering from protein deficiency. In the (then) Belgian Congo, Vanbreusghem examined thousands of children and found that its prevalence varied between 5 and 40 per cent. It was higher in areas where serious protein deficiency was known to occur and kwashiorkor was present. The same applied to cases treated in hospital: in Bukavu, 89 per cent of the children suffering from kwashiorkor were infected with ringworm. At present it is impossible to say whether this arises from a lack of vitamin A accompanying protein deficiency, a change in the sebaceous secretion of the scalp, or some abnormality of the skin or hair related to kwashiorkor and favouring the development of fungi.

In North Africa, in some parts of Central Africa, in the Eastern Mediterranean basin, in certain parts of the United States where there is a high percentage of Negroes, and in various parts of eastern Europe, ringworm may affect 30–40 per cent of the children. The health authorities of several countries have decided to attack this problem and the World Health Organization is giving assistance to the Province of Syria, the United Arab Republic and to Tunisia. In Yugoslavia, where a systematic campaign against ringworm is under way, the Organization has assisted a demonstration project of mass griseofulvin treatment, directed by Prof. E. I. Grin. The campaign being carried out and a general survey on ringworm and its treatment are outlined in a recent issue of the *WHO Chronicle**.

The dermatophytic fungi (*Trichophyton, Microsporum*) live and multiply at the expense of the keratin they digest; as a result, the growth of the hair is impaired and it falls out, leaving bald patches.

The treatment used until quite recently consisted in desquamation of the parts affected so as to remove the diseased keratin, and the disinfection of the patches in order to prevent contamination of newly formed keratin. For this purpose, fungicidal ointments and pomades, and even X-ray therapy, which causes depilation, were employed. None of these methods gave reliable and permanent results. It was necessary to find a new treatment, acting internally instead of externally, that would enable keratin-producing cells to resist the fungus, and continue to resist it after they had become keratinized.

The discovery of griseofulvin provided an antibiotic satisfying these requirements. Isolated in 1939 from *Penicillium griseofulvum*, then from several other species of *Penicillium*, the antibiotic was identified chemically and used in horticulture against certain fungal plant pathogens. Its powerful fungistatic action attracted the attention of dermatologists, and, starting in 1958, investigations were carried out on its use in the treatment of certain human and animal dermatomycoses. The antibiotic gave better results than any form of treatment previously applied. It was more active when administered orally than parenterally, was not found in the serum of treated subjects, but, on the other hand, could be detected in their hair. In therapeutic doses it did not have any harmful or irreversible side-effects. As a result of these outstanding properties it was decided to use it for mass treatment.

Following mass immigrations from highly endemic areas after 1948, ringworm, which had been almost unknown in Israel, again developed into a public health problem. The number of new cases reached 4,000–6,000 per annum. The good results obtained elsewhere with griseofulvin encouraged Israeli health authorities to adopt it for a mass campaign, after confirming its effectiveness and harmlessness in a preliminary trial with a group of women and children in hospital at Tel-Hashomer.

---

* *WHO Chronicle*, 15, No. 2; February 1961.

Those most seriously affected are children aged 5–14 years. Although in most cases the condition clears up spontaneously at puberty, some victims bear the marks of the disease throughout their lives.

Trichophyton violaceum is the most widespread parasite ; favus caused by *T. schoenleini* is also encountered. In the Arab village where the campaign was carried out there were 441 *T. violaceum* and 5 *T. schoenleini* cases. Griseofulvin was administered in single doses of 25/30 mgm./kgm. of body weight a day. At the end of three weeks there was a marked improvement in most cases. After eight weeks, 99 per cent of the *T. violaceum* infections and 60 per cent of the *T. schoenleini* infections were cured. All cases were cured after treatment for ten weeks. Twenty-five cases which were followed up after 2–6 months did not suffer any relapse.

DYNAMICS AND ENERGETICS OF SWIMMING IN WATER-BEETLES

By Dr. WERNER NACHTIGALL

Strahlenbiologisches Institut der Universität, Bavariaring 19, München

KINEMATIC and dynamic measurements[1] were carried out on *Acilius sulcatus* L. (Dytiscidae). The resistance coefficient c_w of the *Acilius* torso, as a criterion of its flow adaptation, amounts to 0·23 for a Reynolds' number, R_e of 5×10^3 to 8×10^3. Consequently, *Acilius* produces only 5·75 times as much resistance for a given velocity as a drop-shaped body of best adaptation, having a comparable frontal area, but only half as much as a corresponding ball. This very favourable value results from the dorsoventral flattening of the body, the greatest height of which lies in the front third and the greatest width in the rear third of the body, where the epipleura are pulled out so that the borders are sharp. There is no essential difference in velocity between dorsal and ventral flow, and there is no enlargement of the resistance coefficient by a smaller R_e as a result of the preformed places of vortex separations (Fig. 1). The body ends in a half-round edge ; this hinders the vorticity of the plane separating dorsal and ventral flow. Measurements prove the hydrodynamic efficiency of this body-form ; the resistance rises to about 120 per cent if the flow comes from behind, and to about 122 per cent if the edge is cut off. This body-form also possesses excellent swimming stability.

The single propulsion factor is the part of rudder-stroke force consumed by metapodial swinging that lies in the direction of movement, the forward drive. With each rudder-stroke, the forward drive impulse, I_R, that is, the time integral of the propulsive force during the rudder stroking, is reduced by the counter-drive impulse, I_V, which results from the forward pulling of the metapodials. The fraction of the total impulse available for propulsion, $\eta = I_R/(I_R + I_V)$, is the efficiency of underwater swinging as a propulsive factor. It can equal 1·0 in an ideal situation and it can be determined graphically in a complicated way for the stationary (η_1) and freely swimming (η_2) animal as follows : slow-swimming movement, $\eta_1 = 0{\cdot}84$, $\eta_2 = 0{\cdot}72$; medium-swimming movement, $\eta_1 = 0{\cdot}87$, $\eta_2 = 0{\cdot}78$; fastest-swimming, $\eta_1 = 0{\cdot}91$, $\eta_2 = 0{\cdot}81$. The η values for freely swimming animals are somewhat lower than for stationary ones, since the pulling forward of the metapodials happens in water which is moving in relation to the swimming animal. The faster the animal swims, the better is the efficiency ; the greater the applied power, the better it is utilized. The levels of efficiency are surprisingly high with an average of 80 per cent. This is explained by the morphological and kinematic peculiarities of the metapodials.

In the rudder-stroke the surface of the leg, F, and the stroking speed, v, are large. Therefore, the induced resistance W, proportional to Fv^2, is very high. The leg stands with broad sides and with swimming hairs spread perpendicular to the direction of stroking ; v is usefully maximal, when the leg is perpendicular to the median. During the 'partial thrust time' the expended force is changed in propulsion from 98 per cent to 100 per cent, and further to 70 per cent. The resulting harmful side-force amounts to a maximum of only 23 per cent of the forward drive.

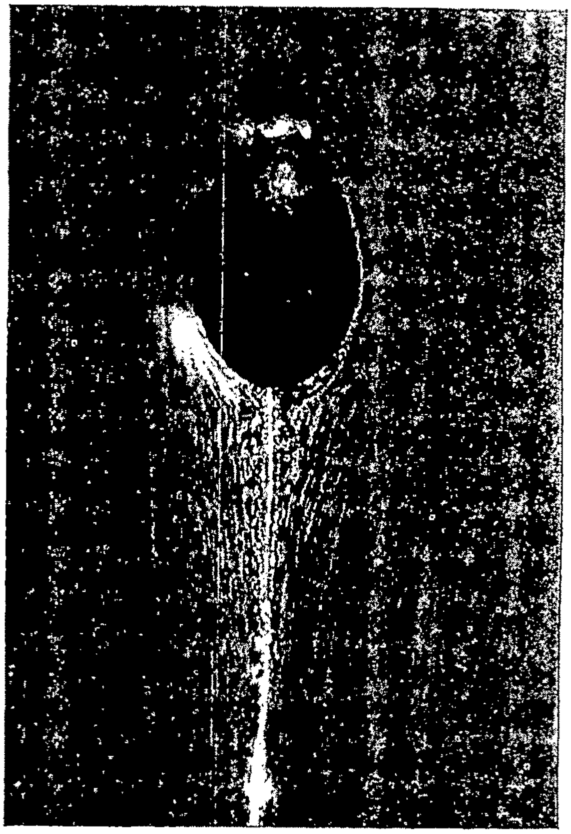

Fig. 1. *Acilius sulcatus*, L. Flow around the frontal area ; taken with an associated reference system at $v = 35$ cm./sec. The laminar flow changes at the widest position of the torso into turbulence. The eddying (and therefore the resistance) is moderate ($R_e = 6{,}000$)

When the metapodials are pulled forward, v is somewhat smaller (an average of 90 per cent of the rudder-stroking speed); F becomes extensively reduced through the collapse of the swimming hairs and the forward-pulling of the leg close to the body, which first is turned around in the highly resistant rudder-position, when the body-speed has reached its minimum. Therefore, according to the above, the resistance generated by the forward-pulling of the leg is small; compared with the outstretched rudder-leg (100 per cent) it amounts to only 6·2 per cent by drawing after, 14·4 per cent by pulling forward close to the body and 31 per cent by turning into the new rudder-position.

The tarsus, also possessing swimming hairs, performs the chief propulsion, namely, 81·8 per cent of the total forward drive compared with 16·9 per cent of the tibia and 1·3 per cent of the femur. According to careful measurements, the part of total forward drive produced by the swimming hairs alone amounts to 67·7 per cent. Furthermore, they raise the forward drive of the solid leg to 230 per cent, the counter drive only to 45 per cent and consequently the effective forward drive to 300 per cent. Therefore, as 'split surfaces' they constitute an excellent rudder principle (Fig. 2). Besides, they move automatically and therefore they consume no muscle force. Moreover, through their uneven distribution, they turn the tarsus at the start of rudder-stroking automatically into working position. They occupy 79·8 per cent of the leg surface, and, with a 67·7 per cent total forward drive component, they attain 54 per cent of the forward drive of an equally large uninterrupted surface. They attain the basic advantage of their mobility and automatic movement as a result of their lattice arrangement with a loss of only 46 per cent of the forward drive against the theoretical maximum. The leg-thrust amounts to 480 per cent of the body resistance. So, for the *Acilius* torso, the rudder legs are very efficient locomotive organs.

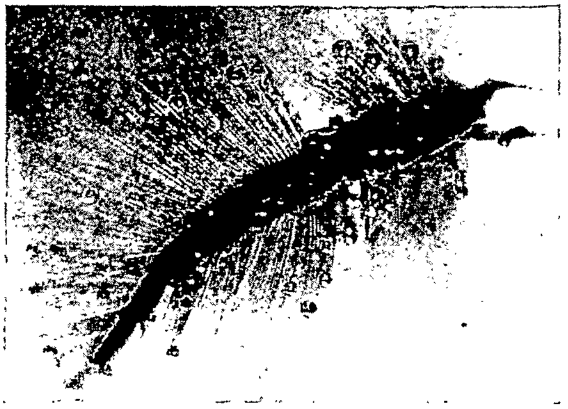

Fig. 2. Left metapodium of *Acilius sulcatus* L. at rudder stroking. The manner of the distribution of the swimming hairs and the spread, as also the enormous enlargement of the stroking area, are completely defined (taken in a flow apparatus)

The smaller the rudder-energy E_R, the greater is the energy available for other body-processes E_x, since the sum of these is equivalent to the total available energy, E. Only a fraction of the rudder energy E_R is used for the production of work, which is useful for locomotion, as a result of vorticity (η_1), through lateral drive (η_2) and counter-drive (η_3). It has been determined that $\eta_1 = 0·50$, $\eta_2 = 0·77$ and $\eta_3 = 0·80$; consequently, the total level of efficiency, $\eta_{\text{total}} \approx 0·30$. 70 per cent of the mechanical energy produced is lost in the leg movement itself. For a muscle efficiency, $\eta_4 = 0·30$, becomes $\eta_{\text{chem.}} = 0·10$. That is, the available chemical energy is transformed into work for locomotion to the extent of 10 per cent. Comparing the minimal chemical energy which is calculated for swimming at speed v with the total available energy which can be determined from respiration measurements at resting turn-over, it follows that *Acilius* expends 100 per cent when $v = 25–30$ cm./sec. (flight), 42 per cent when $v = 20$ cm./sec. (fast continual swimming), 2 per cent when $v = 7$ cm./sec. (slow continual swimming), only 5 per cent by normal distribution of movement and with a warm atmospheric condition; with a cool atmospheric condition it expends only 1 per cent of its available energy corresponding to the resting turn-over. This means that in daily life no notable energy losses result through locomotion ($E \gg E_R$; $E_x \approx E$), but, if necessary, extremely fast swimming is possible under optimal use of this great energy (flight, seizing of plunder; $E \approx E_R$). With *Paramecium*[2], the corresponding values amount to ½–12 per cent, with jumping grasshoppers[3] 100 per cent, and with running suckers[4] 60–100 per cent. With running insects they have not been investigated, but certainly they are less favourable. The quoted dynamic and energetic sizes present for the first time a quantitative idea of the excellent adaptation of water insects to the flowing medium.

COSMIC RAY AGES OF THE TREYSA AND SIKHOTE-ALIN METEORITES

By DAVID E. FISHER

Department of Engineering Physics, Cornell University, Ithaca, New York

IT has been proposed[1,2] that the cosmogenic production-rate, dependent on depth, of stable nuclides in iron meteorites can be estimated from the measured rare gas ratios. One of the criticisms that has been directed at the scheme[3] is that (while it incorporated experimental data on the Sikhote-Alin and Treysa meteorites) different exposure ages were assigned to these meteorites; whereas, it is claimed, direct measurements[4,5] lead to approximately equal ages.

On re-examination of the data, an error was found in our calculation of the helium-3 production-rate in

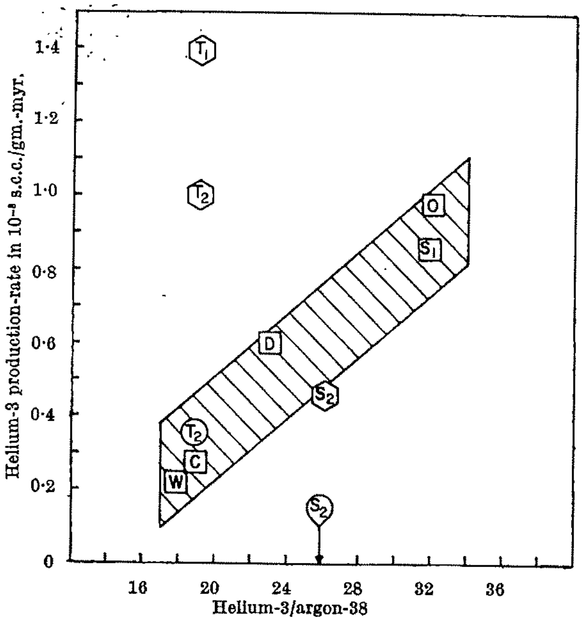

Fig. 1. Production-rate of helium-3 plotted against ratio of helium-3/argon-38. The squares are calculated from chlorine-36 data, the hexagons from argon-39 data, and the circles from tritium data. *O*, Odessa (ref. 10); S_1, Sikhote–Alin (ref. 10); S_2, Sikhote–Alin (ref. 4); *D*, Canon Diable (ref. 10); *C*, Carbo (ref. 10); *W*, Williamstown (ref. 10); T_1, Treysa (ref. 5); T_2, Treysa (ref. 4)

Treysa. The corrected scheme is shown in Fig. 1. New data on the tritium content of Treysa and Sikhote–Alin are included, although relative cross-sections for helium-3 and tritium production are not well known.

It is apparent that the scheme does not account for the argon-39 data on Treysa, nor for the tritium data on Sikhote–Alin. It has been pointed out[4] that no accepted model of cosmogenic nuclide production can account for the low tritium/argon-39 ratio in these two meteorites. It was suggested that diffusion loss of tritium is responsible for the anomalous value of this ratio. This suggestion is compatible with Fig. 1 for the low value of the tritium content in Sikhote–Alin, but not for the Treysa data (Sikhote–Alin is of the coarsest octahedrite structure, while Treysa is a fine octahedrite).

It is emphasized that Fig. 1 is merely an observation of an apparent correlation between radioactivity and rare-gas measurements. Future data may show the correlation to be coincidental or due to errors in measurement, in which case the scheme will be rejected. However, the low tritium/argon-39 ratio in Treysa may be due to an excess of argon-39. It has been noted[2] that, if one attempts to organize the rare-gas data for all the measured iron meteorites, particular ratios in particular meteorites seem to be anomalous. It was suggested that these anomalous values were due to secondary reactions on trace elements. For example, the excessively high value of the neon-21/argon-38 ratio in Tucson was tentatively ascribed to the ^{24}Mg$(n,\alpha)^{21}$Ne reaction, a larger amount of magnesium being present in this meteorite than in others. Similarly, the ^{39}K$(n,p)^{39}$Ar and the ^{40}Ca$(n,2p)^{39}$Ar reactions would lead to an excess of argon-39, and it is suggested that an excess of these elements in this meteorite may be the reason for the variation of the Treysa data from the proposed scheme.

In iron meteorites the argon-38/argon-36 ratio is generally about 1·6. In stone meteorites, with an iron/calcium/potassium ratio of about 100 : 6·5 : 0·4, the argon-38/argon-36 ratio reaches approximately 2, due primarily to the calcium isotopes. In Treysa this ratio varies from 1·52 to 1·75. This implies maximum calcium and potassium abundances relative to iron in Treysa of about 100 : 2 : 0·2. This limit does not prohibit the postulated argon-39 effect. Stoenner and Zahringer[6] have reported that the potassium content of iron meteorites may be extremely inhomogeneous; this may be a factor in the disparate values for argon-39 content of Treysa reported in refs. 4 and 5. Then a more nearly correct value for the exposure age of Treysa might be obtained by taking the nuclide production-rate from Fig. 1 than by using the argon-39 data.

Table 2. COSMIC RAY AGE OF THE SIKHOTE–ALIN METEORITE, IN UNITS OF 10^9 YR.

Source of data	^{38}Ar–^{39}Ar	^{36}Ar–^{36}Cl	^{3}He–^{3}He/^{38}Ar (Fig. 1)
Ref. 4	0·22 (0·42)		0·17
Ref. 10 (^{36}Cl) Ref. 7 (rare gases)		0·17	0·15
Ref. 11		(0·12)	

In Tables 1 and 2 the exposure ages for Treysa and Sikhote–Alin are calculated again, using all available raw data on rare gas, tritium, scandium-45 and chlorine-36 measurements. The ages in parentheses are those deduced in the original papers. The differences arise because of the following considerations: (1) Fireman and DeFelice assumed an argon-38/argon-39 cross-section ratio of 1·5; recent data indicate a nearly constant ratio of about 2 from 0·43 × 10^9 to 6 × 10^9 eV. They estimated a helium-3/argon-38 ratio of 20 for all iron meteorites; according to their estimate of the helium-3/helium-4 ratio, to Schaeffer and Zahringer[7], and to Vinogradov *et al.*[8], this should actually be about 26 in their sample of Sikhote–Alin. (2) Wanke and Vilcsek[5] used a value for the cross-section of argon-39 equal to 5 mb. Recent measurements indicate a value of 6·5 mb. at 0·7 × 10^9 eV. rising to 12·4 mb. at 6 × 10^9 eV.; a value of 10 mb. was used here.

The spread in the ages listed in Tables 1 and 2 reflects both the different experimental values for measurements of the same nuclide in the same meteorite by different investigators, and the uncertainty in the assumptions necessary in proceeding from the measurements to calculations of the exposure age. It is a measure of the errors involved, and would indicate that calculations, leading to such quantities as cosmic ray intensities from these data, contain an element of uncertainty. The ages proposed as 'best' are 0·16 × 10⁹ yr. for Sikhote–Alin and, for Treysa, 1·3 × 10⁹ yr. if Fig. 1 is used to estimate the nuclide production rate; 0·35 × 10⁹ yr. if the argon-39 data are accepted as indicating the primary flux.

IMPULSE LOADING OF ROCK TARGETS TO PRODUCE FRACTURE PATTERNS SIMILAR TO NATURALLY OCCURRING RADIAL DYKE SYSTEMS

By CARL F. AUSTIN

New Mexico Bureau of Mines and Mineral Resources, New Mexico Institute of Mining and Technology, Socorro

DURING investigations of the impulse loading of rock and earth materials, a striking similarity was noted between fractures induced by impulsive loads in some rock types and the great dyke swarms occasionally encountered in volcanic provinces.

The impulse loading of a rock material can be accomplished in many ways. A simple method of delivering large amounts of energy to a small target area is to strike the target with a jet derived from a lined-cavity shaped charge. Such a jet-target impact creates a narrow empty hole in the rock target, referred to generally as a penetration. Under suitable conditions of target confinement, the penetration is accompanied by fractures filled or intruded by metal and metal oxides from the shaped-charge jet.

For fracture studies a jet was desired the metal fragments and oxidation products of which would contrast boldly in appearance with the target material. A light greyish-white limestone target rock was selected, previous experimental work[1] having indicated that limestone was an ideal target rock for fracture research. Thus, cast iron was chosen as the jet material because this metal appears dark in a light target, and in addition yields a dark grey-black oxide upon high-velocity impact. Such a colour contrast is especially important for fracture work. Those fractures definitely opened during and immediately following penetration are filled with liner metal and oxides, and are easily distinguishable from cracks created by handling the fractured target during its sectioning and study. Reliance on coloured fracture fillings means, however, that fractures that never were filled by metal and oxides are indistinguishable from both pre- and post-penetration cracks in the target.

To achieve high projectile velocities and obtain a large amount of target response to impact, heavy cast-iron liners were fired into limestone targets, with use of the simple lined-cavity shaped-charge design illustrated in Fig. 1. This charge design produces a 1-in.-diam. jet of small, sharp, cast-iron particles. The front tip of this heavy jet travels at a velocity of about 21,800 ft. per sec. (velocity across a course of 1·088 ft. extent; course located 2 ft. in front of the shaped charge). Fig. 2 is a flash X-ray photograph (exposure time 1 µsec.) of a cast-iron jet from a shaped charge of the type shown in Fig. 1.

The targets used for this work were composed of relatively fine-grained, crinoidal Pennsylvanian limestone (Madera). Table 1 tabulates the physical properties of the target. Rock targets for impulsive-

Fig. 2 (right). A cast-iron jet derived from a charge of the design shown in Fig. 1 (exposure time 1 µsec.)

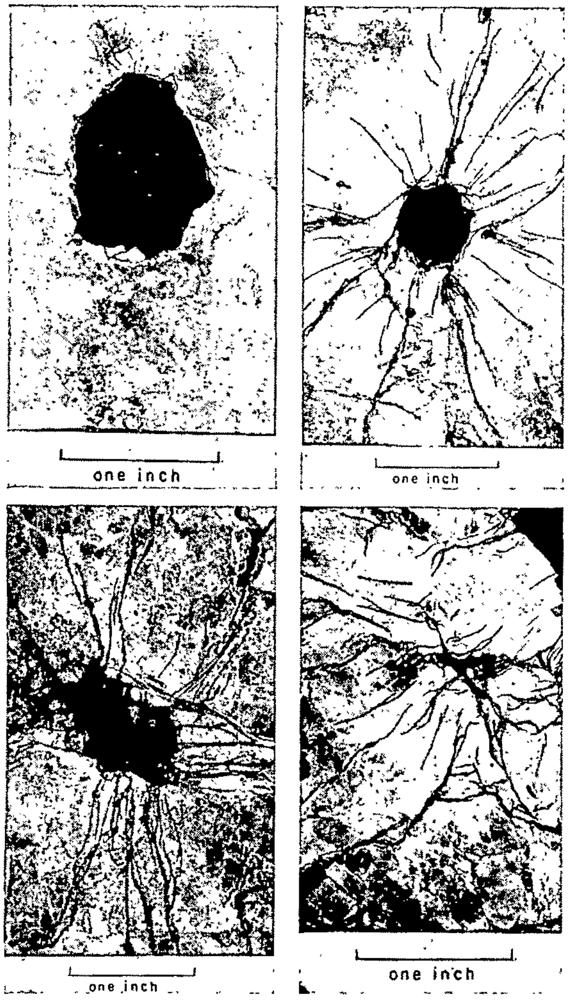

Fig. 3. (upper left) Result of firing a jet into a massive, uncracked limestone target; (upper right) the radial fracture pattern formed as a result of firing a jet into a cracked limestone target; (lower left) the typical fracture swarms formed at right angles to the walls of an angular penetration in a cracked limestone target; (lower right) the fracture complex formed beneath a penetration made in a cracked limestone target.

load investigations of the present type must not be permitted to break into a few large discrete fragments but must be kept essentially unbroken. To prevent fragmentation in a brittle target with such a low tensile strength as that of rock requires very massive targets or very heavy confinement. Massive limestone outcrops in place in the Earth's crust were used for the experiments reported in this article, making confinement laterally and into the target virtually infinite. Targets were able to expand only locally through the closing or tightening of pre-penetration cracks and joints, and perhaps to a minor extent through local decreases in porosity. Experiments so far suggest strongly that the presence of pre-penetration cracks is essential to formation of fractures intruded by jet metal and oxides. Where such cracks are lacking, no significant metal- or oxide-intruded fracture patterns developed in the targets.

Following the loading of the target to create a fracture system, a routine procedure was followed to prepare the target for study. Melted paraffin was poured into the target and allowed to solidify in order to preserve the detail of the penetration walls and help maintain the coherence of the fractured target. The paraffin was added, immediately following penetration of the target, while the target was still slightly warm. (Interestingly, rock penetrations are not hot but only mildly warm.) Next, a percussion-type rock drill was used to drill a double ring of holes surrounding the area of penetration and fracturing. Generally, in view of the type of jet used for penetration, a 1-ft. radius was used. The holes were drilled as close together as possible and slightly deeper than the expected depth of penetration. Following drilling the intervening rock was removed by hand to leave a cylindrical plug of rock containing the fractured area to be examined. Several holes were then drilled into the plug of rock at its point of attachment to the main rock outcrop, and the entire cylindrical plug was broken free as a single piece of rock. This was taken to the laboratory, where it was cut with a power hacksaw into a convenient rectangular block, mounted in plastic, and sawed into ¼-in.-thick slices. The slices were made at right angles to the axis of the penetration, permitting the development of a rather complete three-dimensional picture of the target fracturing that accompanied the jet penetration.

Jet firings into limestone have so far illustrated three basic fracture patterns when the fractures are cut by a plane perpendicular to the axis of the penetration. These are: (1) penetration with essentially no fracturing; (2) radial patterns around a circular or elliptical penetration; (3) patterns with the fractures at right angles to the walls of a penetration having a rectangular or angular cross-section. No metal- or oxide-filled fractures occur in truly massive targets. Given a limestone with no pre-penetration cracks, and thus being unable to expand slightly about the penetration, no metal- and oxide-filled fractures will form. Simple metal- and oxide-filled radial fracture systems are found surrounding penetrations that occur in previously cracked

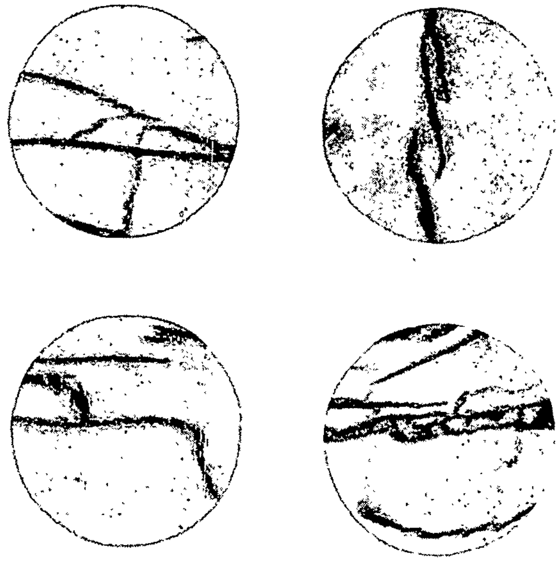

Fig. 4. Fine structure of individual metal- and oxide-filled fractures in a limestone target. The upper left photograph shows the microscopic en echelon character of macroscopically linear fractures; the upper right photograph shows macroscopic en echelon fracture alignment; the lower left photograph shows the typical abrupt junctions between fractures; the lower right photograph shows the rubble-filled character typical of relatively wide fractures

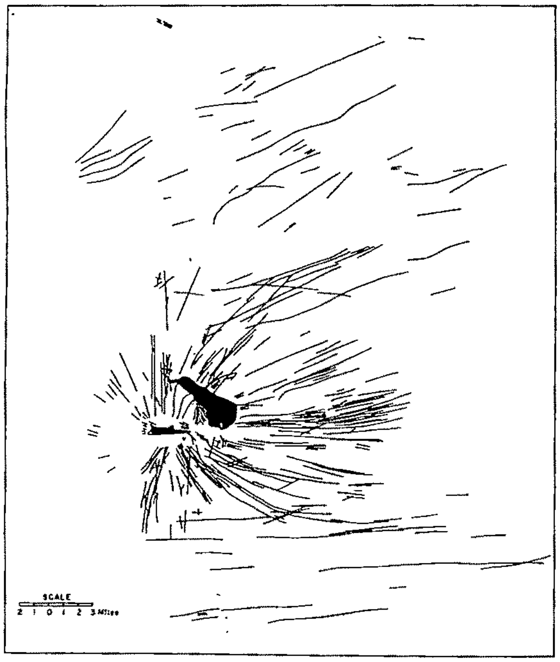

Fig. 5. The dyke swarms of the Spanish Peaks area in Colorado (western United States). Dark areas are intrusive centres, dark lines intrusive dykes. (Adapted from Knopf, ref. 2)

targets. In the case of a target with a pre-penetration crack cutting the penetration at an angle, fracturing begins on the side nearer the crack. In rocks with cracks scattered about the target area, relatively symmetrical fracture patterns are formed during the penetration process. Penetrations tend to become rather angular and irregular in outline towards their bottoms, instead of circular or elliptical. In the bottom areas the fractures resulting from the penetration process appear as swarms at right angles to the walls of the penetration. Although not examined in detail, the evidence at hand suggests that the fracturing immediately below a penetration is very complex. Fig. 3 illustrates the three types of fracture systems, as well as a section showing the complexity at the bottom of a penetration. Fig. 4 presents the fine structure of individual fractures.

Fig. 5 shows the great dyke swarm of the Spanish Peaks area in the western United States. A comparison of this figure with fracture patterns of Fig. 3 exhibits obvious similarity between the natural and artificial fracture-intrusion patterns.

In view of the foregoing similarities in fracture and intrusion patterns and the ease of formation of fracture patterns in rock models, I am continuing my work on the impulse loading of rock and earth materials.

ACTIVATED NATURAL CRYSTALS

By Dr. GIOVANNA MAYR
Faculty of Medicine, University of Milan

SUCCESSFUL results have been obtained with tritium and carbon-14[1] and also in experiments with lead[2], in which it was found that when a substance is placed in contact with a source in the form of a solid-labelled compound, the active substance can be found after some time at a distance from the source that cannot be explained on the basis of ordinary diffusion. These results suggested more general experiments to test the phenomena with other active sources and different kinds of substances for activation, particularly crystals.

The sources used were : calcium-45, carbon-14, phosphorus-32 and sulphur-35, prepared using materials supplied by the Radiochemical Centre, Amersham. The activity of each source was, at the beginning of the experiments, about 250 μc. As for the crystals, the inactivity of which was previously checked, in almost all the experiments slices were used about 2–3 mm. thick, cut in different directions ; in several cases it was also possible to make measurements of differently orientated slices cut from the same crystal. The specimens were : apatite (perpendicular to the z-axis and parallel to the same) ; calcite (perpendicular to the optic axis and parallel to a rhombic face) ; celestine (perpendicular to the x-axis and parallel to the same); gypsum (parallel to cleavage) ; pyrite (parallel to a cube face and parallel to a dodecahedral face).

The activation was produced by applying the slice of the crystal to the source for a time ranging from a few days to several weeks. At the end of the exposure the slice of crystal was taken off and counted on both faces, in some cases—when the activity was high—at a Geiger end-window counter ; in other cases at a gas-flow counter. In all cases activity was evident ; much stronger on the 'contact surface', that is, the face that had been kept in contact with the source, than on the 'opposite surface'.

The measurement of these activities was repeated at different times after the end of the exposure (several weeks and also several months). In all experiments done until now, activity was detected.

Besides this, the activated crystals were autoradiographed using Ilford G_5 nuclear emulsions ; a photographic effect was always noticed. Generally, the crystals were activated by exposure to a source, the active element of which was of the same chemical kind as some of the elements contained in the molecules of the crystal (apatite to calcium-45 and to phosphorus-32, calcite to calcium-45 and to carbon-14, gypsum to calcium-45 and to sulphur-35, celestine and pyrite to sulphur-35).

But an attempt was also made to expose a crystal to a source the active element of which was not of the same chemical kind as any of the components of the crystal molecule, but chemically allied to one of them, namely, celestine and calcium-45 ; in this case the effect was rather strong. A further attempt was made by exposing crystals to a source the active element of which was not of the same chemical kind as any component of the molecule nor allied to one of them, namely, gypsum and carbon-14 ; also in this case an activation effect, although a weak one, was noticed.

In order to check if the activation of the opposite surface was actually due to the presence of active atoms and to obviate the effect of possible secondary radiation from the contact surface, the following procedure was adopted : two superimposed slices (cut from the same crystal and equally orientated) were exposed together ; after removal from the source, the slice farther away was tested separately. In each case this showed a weak activity, and this could only be due to the presence of active atoms at a distance from the source corresponding to the opposite surface.

To check if the activity noticed at the opposite face of the activated crystal was due to active atoms having migrated from the contact surface through the crystal or along its surface, and to find out if, and how, the activity passed from the contact surface into the crystal, several crystals were carefully counted again, then weighed, ground on one face, weighed and counted again ; this process was repeated several times and also on the opposite face. Care was taken during each grinding to renew frequently the material used for grinding and to clean thoroughly each ground surface before counting. This technique of grinding has been used in some work on ordinary diffusion[3], but the effect described here is different. In fact, the activity decreased with increasing depth from each surface, but the greatest decrease was noticeable only after the first grinding ; after this, the rate of decrease was much lower and always less, the activity reaching a rather uniform value. This appears in Figs. 1 and 2, which relate to examples that illustrate the general result of experiments of this kind, and refer to the activity measured on both faces of slices of calcite cut perpendicular to the optic axis and cut parallel to a rhombic face.

These activities were measured some months after the end of the exposure and the measurements of the ground surfaces correspond to counts done as soon as grinding had been finished. The activity of the last two ground surfaces of each sample, after a lapse of time, appeared to have increased (probably lattice disorders had occurred during grinding).

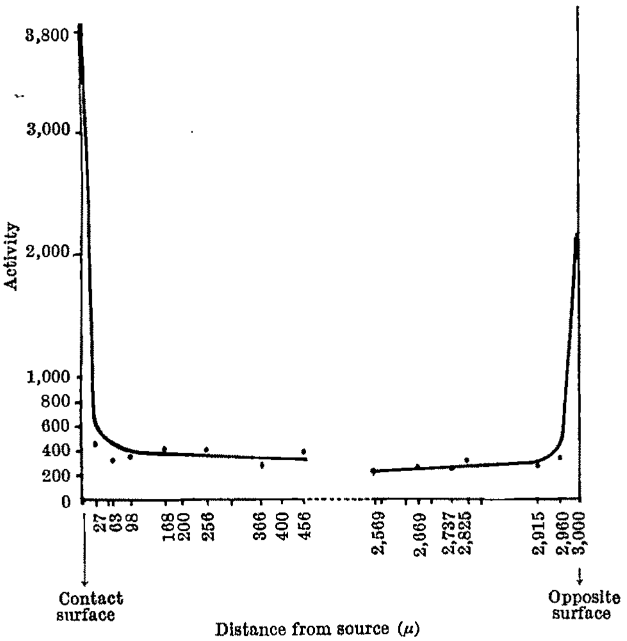

Fig. 1. Calcite cut perpendicular to the optic axis. Distance from source represents distance from contact surface. Activity is net counting-rate ± *S.D.*

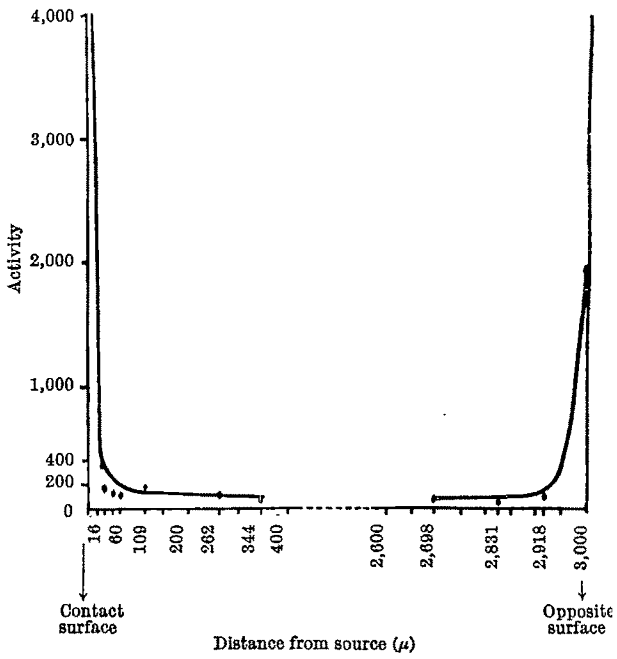

Fig. 2. Calcite cut parallel to a rhombic face. Distance from source represents distance from contact surface. Activity is net counting-rate ± *S.D.*

The result of the experiment demonstrates that the active substance penetrated into the crystal ; at the same time the particularly high activity noticed at both external surfaces of the slices demonstrates that some active substance also migrated along the surface. The magnitude of this effect, calculated on the basis of the activity in the region where it appeared to be more or less sufficiently uniform, assuming that the activity measured corresponds to the radiation emitted from a depth of 150 microns (about three-quarters the range of the beta radiation from calcium-45 in calcite) and correcting for self-absorption, was: 0·0064 μc./gm. (in the first sample with calcite perpendicular) and 0·0022 μc./gm. (in the second sample with calcite parallel).

The difference cannot be ascribed to the different directions alone, since geometry and exposure time were also different.

It has been demonstrated that natural crystals can be activated by simple contact with a radioactive source. It appears that the active atoms migrate and that this effect may be considered as the combination of two effects : (1) a migration through the material in depth (bulk effect) ; (2) a migration along the surface (surface effect). This effect may be explained by the fact that the radioactive substance present in the source produces an excited state : (*a*) in the source itself by means of the radiation emitted and of the recoil of the emitting atoms ; (*b*) in the contacting substances by means of the radiation up to its full range (a region that can be called 'range layer').

Consequently, in the source and in the contacting substances, up to the range layer, breakage of bonds, ionization and knock-on and knock-off of atoms may occur. These facts explain the possibility of atom exchange between neighbouring molecules and, in solids, the production of lattice defects (vacancies and interstitials). This, together with the possibility of intergranular migration, opens the way to a further migration beyond the range layer, which differs from ordinary diffusion, because the concentration at the origin, instead of being constant, increases with time.

A theoretical treatment of these processes, done in collaboration with someone else, leads to conclusions in agreement with the experimental results and will be published separately. Obviously, not only the active atoms migrate, but also all kinds of atoms and ions that have undergone collision, and this may occur from source to contacting substance as well as vice versa.

Therefore, the active element observed in the active crystals by counting will be mixed most probably with the inactive carrier in the same proportion as in the source itself, so that it may be expected that, until saturation is reached, the magnitude of the effect may be proportional to the square of the specific activity of the source.

The effect here described differs from ordinary diffusion, not only because it is explained differently, but also because the experimental conditions are completely different, as neither particularly adherent contact nor heating is required. Further differences concern its magnitude and the two kinds of migration.

The experiments done up to now are not sufficient to give a complete picture of the effect on crystals, but are sufficient to indicate some lines of research : (*a*) The dependence of the effect on the chemical constitution of the source and of the activated substance, as well as on the lattice conditions ; also dependence on crystallographic structure. (*b*) The explanation of some concentric arcs which were noticed on some autoradiographs. I shall be pleased to hear from others who have done experiments of this kind.

This research has been carried on in the Department of Radiotherapeutics of the University of Cambridge. I thank Prof. J. S. Mitchell for hospitality and advice; also Dr. N. F. M. Henry, of the Department of Mineralogy, who kindly read the manuscript of this paper. Also, I thank the Consiglio Naz. le dello Ricerche, which gave grants for my stay in England.

PATTERNS OF PREFERENCE IN EQUIPROBABLE SITUATIONS

By Prof. JOHN COHEN and PETER COOPER

Department of Psychology, University of Manchester

We have previously[1] distinguished two types of gambling situation. In one, the player's skill may, if he so decides, affect his success or failure ; in the other, his skill (or what he believes to be his skill) is confined to making the choice, and once his choice is made, he is unable to do anything to affect the outcome. This second type is the characteristic lottery situation and the one with which we are now concerned. The earlier work was limited to isolated choice situations and not properly systematized. This defect may now be remedied by introducing a new method of representation or 'model'.

All variations of the sorts of choice we propose to study may be represented by assigning suitable values to the symbols :

$$ {}^{r}_{s}D^{w}_{l} $$

where D is the number of draws which the subject can make from a given source (s); w is the number of winning tickets ; l is the number of non-winning tickets; s is the number of sources of tickets ; and r indicates that a ticket drawn from a given source is replaced at random before the next draw.

The experimental procedure required the subjects to choose one of two (or more) possibilities of winning a prize. For example, they could choose to draw once from a box containing ten tickets including one winning ticket, *or* from a box containing a hundred tickets including ten winning tickets : ${}_{1}1^{1}_{9}$ or ${}_{1}1^{10}_{90}$. The instructions varied appropriately from one situation to another. More than six hundred subjects, young and old, took part in these experiments.

Let us now consider the results of the systematic experimental variations in turn :

(i) *Effect of varying 's'* (that is, number of sources or boxes from which the tickets were to be drawn).

The subjects were presented with the following four alternatives:

$$ {}^{r}_{1}10^{10}_{90} \text{ or } {}^{r}_{s}10^{10}_{90} \qquad (1, a) $$

where s took the values 2, 5 or 10.

$$ {}^{r}_{1}10^{10}_{990} \text{ or } {}_{10}10^{10}_{990} \qquad (1, b) $$

$$ {}_{1}1^{1}_{9} \text{ or } {}_{2}1^{1}_{4} \qquad (1, c) $$

$$ {}^{r}_{1}10^{10}_{90} \text{ or } {}_{20}10^{10}_{40} \qquad (1, d) $$

In a further experiment subjects ranked the following situations in order of preference :

$$ {}^{r}_{1}10^{10}_{90},\ {}^{r}_{5}10^{10}_{90},\ {}_{10}10^{10}_{90},\ {}_{20}10^{10}_{40} \qquad (2) $$

The general result was to prefer the alternative with fewer sources. In 1,041 choices, some 68 per cent preferred the alternative in which the ticket was to be drawn from a single source ($p < 0{\cdot}01$).

(ii) *Effect of varying w and l* (that is, the number of winning and non-winning tickets).

Three situations were examined, when p, the mathematical probability of drawing the winning ticket, was 0·1, 0·5 and 0·9 respectively, namely:

$$ {}_{1}1^{w_i}_{l_j} \text{ or } {}_{1}1^{10}_{90} $$

where i, j take the paired values 1,9; 2,18 or 5,45

$$ {}_{1}1^{w_i}_{l_j} \text{ or } {}_{1}1^{50}_{50} $$

where i, j take the paired values 5,5; 10,10 or 25,25 and

$$ {}_{1}1^{w_i}_{l_j} \text{ or } {}_{1}1^{90}_{10} $$

where i, j take the paired values 9,1; 18,2 or 45,5

A preference (statistically significant) was displayed for choosing from the larger total of tickets ($w+l$), when p was 0·1, and from the smaller total when p was 0·5 or 0·9.

(iii) *Effect of varying D* (that is, the number of draws).

The principal choice situations here were :

$$_{1}1_{l_j}^{w_i} \text{ or } _{1}10_{99}^{1}$$

where i, j took the paired values 1,9 or 10,90.

The preferences for one or other alternative seemed to be unstable from group to group except when the number of draws was counterbalanced by a larger value of w, in which case there was a tendency to prefer the latter.

(iv) *Effect of varying the mathematical probability of drawing the winning ticket as well as the value of the prize, proportionately.*

Here the choice was short odds ($p = 0{\cdot}1$) of winning a prize (box of chocolates) or long odds ($p = 0{\cdot}01$) of winning ten boxes. The preference was clearly in favour of the shorter odds. When shillings were substituted for chocolates in another experiment, the preferences for short odds virtually disappeared.

(v) *Points of subjective equivalence of w, l and D.*

From additional data provided by our subjects, it was possible to determine the mathematical probability of drawing a winning ticket when values of w, l and D in the rejected alternative were changed by the subject so as to render the latter as attractive as the chosen alternative. The inference is justified that winning tickets, non-winning tickets and draws are not subjectively valued equally when each is adjusted for equivalence to either of the others in the accepted alternative. Thus the psychological probability attached to draws is less than that attached to winning or non-winning tickets; and assessments of l are more realistic than assessments of w or D.

(vi) *The problem of transitivity of preference.*

When our subjects' preferences are studied over sets of different choices, some 15 per cent appear to be intransitive in the strict sense. In fact, however, the psychological value or 'utility' of any alternative is not constant but may vary according to the alternative with which it is juxtaposed. It follows, therefore, that the use of a notation which suggests invariance (A is preferred to B, B to C, therefore A to C) would be a misapplication of the principle of transitivity. Thus, for example, $_{1}1_{9}^{1}$ may be preferred to $_{1}1_{90}^{10}$ because of a smaller l; and $_{1}1_{90}^{10}$ may be preferred to $_{1}10_{99}^{1}$ mainly because of a larger w. But $_{1}10_{99}^{1}$ may still be preferred to $_{1}1_{9}^{1}$ because of the larger D.

General conclusions.

The notation we have introduced enables the experimenter to represent a great variety of situations and also facilitates the interpretation of the results.

Two generalizations may be hazarded :

$$ {}_{s}^{r}D_{l_i}^{w_i} \text{ is preferred to } {}_{ns}^{r}D_{l_j}^{w_j} \qquad (1)$$

$$\text{when } l_i > w_i,\ l_j > w_j,\ l_i \geqslant l_j$$

$$ {}_{s}D_{l}^{w} \text{ is preferred to } {}_{s}D_{nl}^{nw} \qquad (2)$$

$$\text{when } p > 0{\cdot}1$$

These may be explained on the ground that when the chances of success are smaller than the chances of failure, the majority of our subjects concentrate on the possibility of winning. They prefer, therefore, to rely on a concentration of winning tickets in fewer sources; and they prefer a large aggregate of winning tickets to a small aggregate of non-winning tickets.

When, however, the chances of success are equal to or greater than the chances of failure, most of our subjects concentrate on the alternative with an absolutely small number of non-winning tickets. They prefer to rely on a dilution of the non-winning tickets in a larger number of sources, and they prefer a small aggregate of non-winning tickets to a large aggregate of winning tickets.

When $w = l$, the choice situation clearly discriminates between two types of person: one with a desire to maximize the chances of success and the other with a desire to minimize the chances of failure. This discrimination may prove to have important diagnostic value in clinical psychology and studies of 'personality'.

In general, the preferences seem to be based neither on the relative values of D, w and l nor on their absolute values, but on some combination of relative and absolute values. This is consistent with the results of our earlier quantitative studies of meaning[2]. Such preferences may reflect a combination of relative and absolute psychological phenomena which have hitherto been regarded as autonomous (for example, in Weber's law and the perceptual constancies). This and other theoretical questions of choice in equiprobable situations will be discussed in a full report of the investigation to appear elsewhere[3].

A PHYSICAL THEORY OF CARCINOGENESIS BY AROMATIC HYDROCARBONS*

By DR. J. B. BIRKS

The Physical Laboratories, The University, Manchester

A NUMBER of aromatic hydrocarbons can induce cancer when injected into or painted on to the skin of a mouse. These compounds, which are also carcinogenic in other sites and in other animals, have been called primary carcinogens[1] to distinguish them from the secondary carcinogens, such as the 4-aminostilbenes and azo-compounds, which are more specific in their biological activity, and which probably act through metabolites.

It is observed that there is a significant correlation between the carcinogenicity index and the energy E_1 of the 1st excited π-singlet state of the molecule[2]. An analysis of data[3] for 66 hydrocarbons and 1 : 2-benzanthracene derivatives is shown in Fig. 1. It is found that 22 of the 23 carcinogens considered have $E_1 = 3{\cdot}04 - 3{\cdot}20$ eV. (24,800 – 25,950

---

* Paper read at a meeting of the British Biophysical Society, London, December 1960.

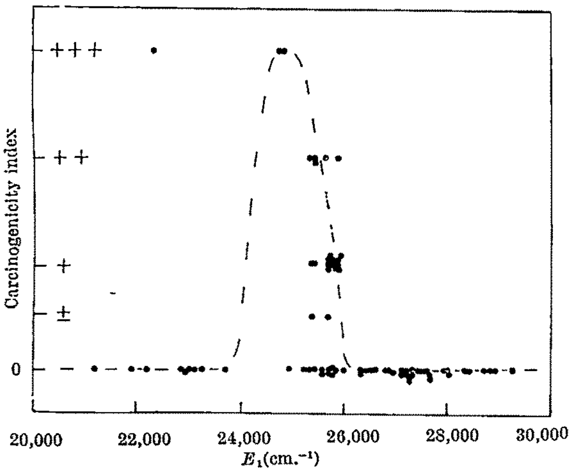

Fig. 1. Polycyclic hydrocarbons and 1 : 2-benzanthracene derivatives. Carcinogenicity index versus energy E_1 of 1st π-electronic singlet state

cm.$^{-1}$). On the other hand, 12 of the 43 non-carcinogens considered also have E_1 in this 'active' region. The degree of correlation indicates that E_1 is related to the carcinogenicity, but that additional factors, such as protein affinity, may also enter.

The form of Fig. 1 suggests a resonance between the carcinogen molecule and some cellular constituent. A common intermolecular resonance effect observed in aromatic molecular systems is dipole–dipole transfer of π-excitation energy, the theory of which has been formulated by Förster[4]. The rate parameter for dipole–dipole energy transfer is determined by the overlap resonance integral :

$$J = \int f_s(\lambda)\, \varepsilon_A(\lambda)\, \lambda^4 \mathrm{d}\lambda \qquad (1)$$

where $f_s(\lambda)$ is the quantum intensity of fluorescence emission of the sensitizer molecules, and $\varepsilon_A(\lambda)$ is the molar extinction coefficient of the acceptor molecules at wave-length λ.

E_1 is the edge of the 1st singlet π-electron absorption band, which has a mean energy $\bar{E} \simeq E_1 + 0{\cdot}5$ eV. Hence if the carcinogenicity is plotted against $\bar{E}$ a similar curve to Fig. 1 is obtained, but with its peak at $\bar{E} \simeq 3{\cdot}54$ eV., corresponding to a mean absorption wave-length $\bar{\lambda} \simeq 350$ mμ. The one important cellular constituent known to emit efficiently in this spectral region appears to be the essential amino-acid, tryptophan, the emission spectrum[5] of which with a peak at $\lambda = 348$ mμ is shown in Fig. 2.

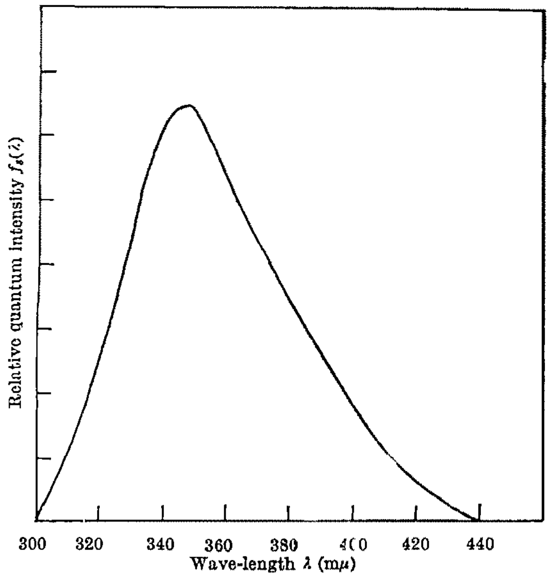

Fig. 2. Fluorescence spectrum of tryptophan

To test the hypothesis that carcinogenesis may be due to dipole–dipole resonance between tryptophan and the carcinogen molecule, as suggested by the above considerations, the overlap integral J has been evaluated, with tryptophan as the sensitizer and the hydrocarbon as the acceptor, for the polycyclic hydrocarbons and 1 : 2-benzanthracene derivatives the absorption spectra[6] of which are known. The results for the methyl derivatives of 1 : 2-benzanthracene are shown in Fig. 3, in which the carcinogenicity index (mean of the Pullman–Pullman[7] indices for painting and injection) is plotted against J, measured in arbitrary units.

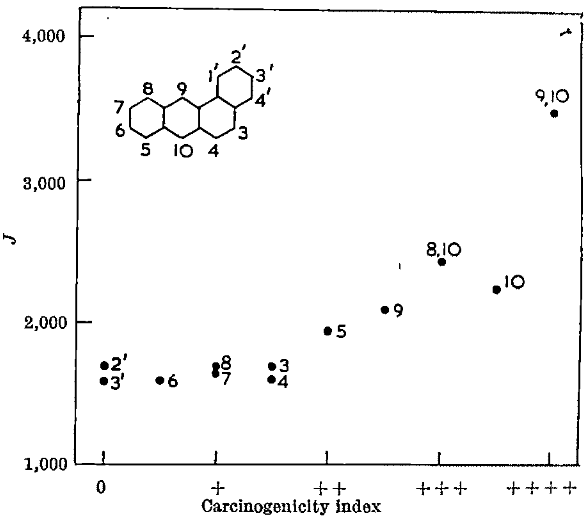

Fig. 3. Monomethyl and dimethyl derivatives of 1 : 2-benzanthracene. Tryptophan overlap integral J versus carcinogenicity index

The methyl 1 : 2-benzanthracenes, which vary markedly in biological activity, have always proved the most challenging and critical group of compounds in previous attempts to correlate some physico-chemical property with carcinogenicity. Pullman and Pullman[7] agree that their electronic theory fails to account for several differences within this group, and they enumerate many other physical and chemical properties that show much less satisfactory correlations. Considering (*a*) the uncertainties in the carcinogenicity data, (*b*) that no allowance has been made for differences between $\varepsilon_A(\lambda)$ and $f_s(\lambda)$ in solution and in the cellular environment, and (*c*) that no account has been taken of the protein affinity of the hydrocarbon, the monotonic relation between J and the carcinogenicity index shown in Fig. 3 is striking. The structurally related potent carcinogens, cholanthrene (+ + + +) and 20-methylcholanthrene (+ + + +), also have high values of $J = 2{,}250$ and $J = 2{,}200$ respectively, consistent with those of the methyl-1 : 2-benzanthracenes.

Heidelberger and Moldenhauer[8] have shown experimentally for a number of aromatic hydrocarbons that the formation of a stable complex with mouse-skin proteins is a necessary, though not a sufficient, condition for carcinogenicity. The outstanding exception to a simple correlation between protein binding and carcinogenic activity is 1 : 2 : 3 : 4-dibenzanthracene, which although non-carcinogenic is as tightly bound as the potent carcinogen, 3 : 4-benzpyrene. The absorption spectrum $\varepsilon_A(\lambda)$ and the 'tryptophan overlap' spectrum $f_s(\lambda)\ \varepsilon_A(\lambda)\lambda^4$ of these two compounds are compared in Figs. 4 and 5. J is only 1,200 for 1 : 2 : 3 : 4-dibenzanthracene, compared with $J = 6{,}200$ for 3 : 4-benzpyrene, showing the major difference in their dipole–dipole resonance with tryptophan.

The values of J and carcinogenicity index for other polycyclic hydrocarbons are listed in Table 1. All the carcinogens have high values of J, with the sole exception of the weak carcinogen 3 : 4-benzphenanthrene, while the non-carcinogens have usually low values of J. Some of the larger non-carcinogenic molecules (for example, pentacene, pentaphene), which have E_1 well below the active region, have anomalously large values of J due to the overlap of their 2nd π-singlet absorption band with the tryptophan emission. If only the overlap with the 1st π-singlet absorption band of the hydrocarbon is considered, and the corresponding overlap integrals J_1 are evaluated, these anomalies disappear. The use of J_1 rather than J appears justified, since the tryptophan emission occurs from the 1st excited π-singlet state which may be expected to resonate with the corresponding excited state of the hydrocarbon. The polarizations of the 1st and 2nd excited states are orthogonal, and it is suggested that the hydrocarbon molecules are bound to the proteins with their axes and planes approximately parallel to those of the tryptophan molecules. Such alignment would greatly enhance the resonance with the 1st excited state, and exclude resonance with the 2nd excited state.

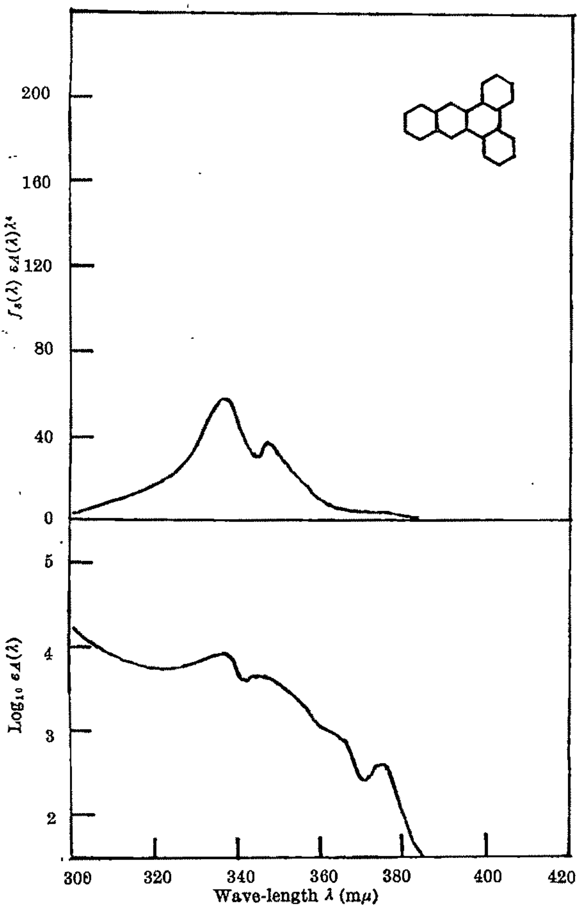

Fig. 4. 1 : 2 : 3 : 4-dibenzanthracene. Absorption ($\log_{10} \varepsilon_A$) and 'tryptophan overlap' ($f_s(\lambda)\ \varepsilon_A(\lambda)\lambda^4$) spectra

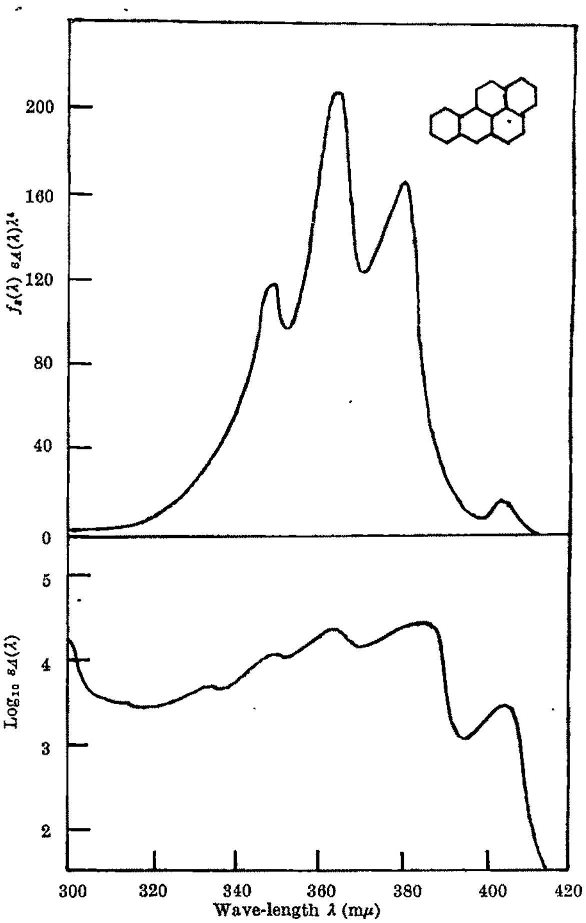

Fig. 5. 3 : 4-benzpyrene. Absorption ($\log_{10} \varepsilon_A$) and 'tryptophan overlap' ($f_s(\lambda)\ \varepsilon_A(\lambda)\lambda^4$) spectra

On the basis of the close correlation observed between J_1 and carcinogenicity, it is proposed that a primary carcinogen should satisfy two fundamental conditions : (1) it should form a bound complex with protein ; (2) its first singlet π-electron absorption band should overlap strongly the emission spectrum of tryptophan, yielding a high value of J_1. Neither of these conditions requires that the primary carcinogen should necessarily undergo any chemical

Table 1. POLYCYCLIC HYDROCARBONS : TRYPTOPHAN RESONANCE INTEGRALS AND CARCINOGENICITY

	J	J_1	Carcinogenicity
Benzene	0	0	0

3 : 4-benzphenanthrene	400	400	+
Chrysene	500	500	0
1 : 2 : 3 : 4-dibenzanthracene	1,200	~1,000	0
1 : 2-benzanthracene	1,350	1,350	?
Anthracene	1,550	1,550	?
1 : 2 : 7 : 8-dibenzanthracene	2,950	~1,900	+
1 : 2 : 5 : 6-dibenzanthracene	3,350	~2,400	++
3 : 4 : 8 : 9-dibenzpyrene	3,600	~2,500	++++
1 : 2 : 3 : 4-dibenzpyrene	5,700	~3,300	+++
3 : 4-benzpyrene	6,200	~6,000	++++
Pentacene	2,600	0	0
Pentaphene	7,750	~100	0

change, thus distinguishing the present theory from alternative biochemical theories of carcinogenesis. This is consistent with the observations of Peacock, Beck and Anderson[9], who found that 3:4-benzpyrene persisted in its original form in mouse skin tissue over a period of 4 months, during which tumour initiation occurred. They concluded that the chance of inducing a tumour varied directly as the persistence of unchanged benzpyrene at the site of injection.

The proposed theory is consistent with the 'protein-deletion' hypothesis of carcinogenesis, favoured by Haddow[10], which considers that the interaction between carcinogen and protein leads to the loss of function of proteins involved as enzymes essential for the control of growth. The results indicate that the deleted proteins are those containing tryptophan. This is consistent with biochemical observations[11] that mouse tumour tissues are about 20 per cent deficient in tryptophan content compared with normal 'controlled' tissues.

Perhaps the most interesting aspect of the theory is that it indicates that the tryptophan molecules are in their 1st excited π-singlet state at some stage in the normal biochemical process, and that it is the loss of this excitation energy by resonance transfer to the carcinogen which hinders or prevents the protein synthesis.

Note added in proof. Other cellular constituents, notably the DNA and RNA purines, guanine and adenine, also have π-excitation states at ~ 4 eV., and fluoresce weakly at λ ~ 350 mμ. The postulated π-excitation, which is similar to that observed in bioluminescent systems, where it is produced by oxidation, might therefore be associated with the genetic and biosynthetic processes.

Further studies of complex formation and of energy transfer between molecules of biological interest are being made to elucidate more fully the mechanisms of carcinogenesis and other biological processes.

I wish to acknowledge the assistance of Dr. F. H. Read, who evaluated the overlap integrals.

NATURE OF THE 'INFECTIVE RIBONUCLEIC ACID COMPONENT' IN CELLS INFECTED WITH ENCEPHALOMYOCARDITIS VIRUS AND THE 'VIROSOME' CONCEPT

By A. J. D. BELLETT and A. T. H. BURNESS
Virus Research Unit, Medical Research Council Laboratories, Carshalton, Surrey

PHENOL extraction at 4° C. of ascites tumour cells infected with murine encephalomyocarditis virus yields infective ribonucleic acid (RNA), although the latter cannot be extracted from the purified virus by similar treatment[1]. Evidence has been presented that the RNA component in infected cells is a virus precursor[2] synthesized in the nuclei[3] during the eclipse phase; it is not deposited with the virus when crude virus preparations are centrifuged[1], but apart from this little is known of its nature. The nature of this component has been investigated by treatment with ribonuclease and papain and reported here.

Infective RNA treated with ribonuclease did not give rise to virus when added to susceptible cells, although untreated RNA did so[1]. Ribonuclease treatment (1 μgm./ml.) of cells infected with RNA greatly reduced the number of cells releasing plaque-forming virus, even when the enzyme treatment was delayed until 2 hr. after infection (Table 1). On the other hand, ribonuclease treatment of cells infected with murine encephalomyocarditis virus did not reduce the number of cells releasing virus if the enzyme were added at 1 hr. or at 4 hr. after infection (Table 1). This suggests that in the RNA component susceptible to phenol extraction and synthesized between 1 hr. and 4 hr. after infection[2], the RNA itself is not 'free', or in any way accessible to the action of ribonuclease.

This suggestion was further supported by experiments in which a series of concentrations of the enzyme was added to cells 1 hr. before infection, and the infected cells then left to synthesize virus while still in contact with the enzyme. Yields of infective RNA and of infective virus after one cycle of virus growth were determined at each enzyme concentration, as was the number of cells killed by virus (Table 2). Ribonuclease did not significantly decrease the amount of virus produced or the number of cells killed; the infectivity of RNA preparations was only affected at enzyme concentrations equal to or greater than 100 μgm./ml. Phenol extraction may not remove all ribonuclease from preparations containing such a high concentration of enzyme, so

Table 1. EFFECT OF RIBONUCLEASE ON CELLS INFECTED WITH RNA OR WITH VIRUS

Cells treated with:	Cells/ml. forming plaques when tested at the stated time after infection 1 hr.	2 hr.	4 hr.
RNA*	$2\cdot3 \times 10^3$	$1\cdot5 \times 10^3$	—
RNA* then ribonuclease†	$2\cdot0 \times 10$	$7\cdot0 \times 10$	—
Virus‡	$4\cdot8 \times 10^5$	—	$1\cdot2 \times 10^6$
Virus‡ then ribonuclease†	$7\cdot0 \times 10^5$	—	$9\cdot5 \times 10^6$

* Cells 5×10^6/ml.; RNA 5×10^4 plaque-forming units/ml. Number of cells releasing virus calculated as the difference in plaque titre between the whole culture and the supernatant after centrifuging at 500*g* for 5 min.

† Cells incubated with 1 μgm./ml. crystalline ribonuclease for 15 min. at room temperature.

‡ Cells 5×10^6/ml.; virus 5×10^6 plaque-forming units/ml. Number of cells releasing virus estimated by direct plating of cells after antiserum treatment and washing.

Table 2. EFFECT OF RIBONUCLEASE PRESENT DURING VIRUS GROWTH

	Ribonuclease concentration (μgm./ml.) 0	0·1	1	10	100	1,000
Virus yield (plaque-forming units/ml. × 10^8)	2·9	5·5	4·2	4·1	7·5	4·0
Cell death (per cent stained by eosin)	78	92	93	71	74	86
RNA infectivity (LD_{50}/ml. × 100)	150	150	100	150	1·5	0·3

Cells (1 × 10^8/ml.) left for 1 hr. at room temperature with ribonuclease, and then infected with 3 plaque-forming units/cell of murine encephalomyocarditis virus. After 5 min. more at room temperature, the cells were diluted in Earle's saline and kept in suspension culture for 17 hr. The concentrations of enzyme were thus reduced after infection to one-fifth of those shown, although the absolute amounts of infected cells and enzyme remained constant.

that at least some of the loss of infectivity may have been caused by residual ribonuclease attacking RNA 'freed' by phenol extraction. However, even if the effect of the enzyme at high concentration is on the RNA component itself, the latter must be at least 100 times more resistant to the action of ribonuclease than 'free' RNA.

These experiments did not exclude the possibility that ribonuclease cannot penetrate the cell or nuclear membrane, so that the RNA component in its intracellular location is protected from enzyme attack. This seems unlikely, however, since ribonuclease can apparently overcome these barriers in cells infected by RNA preparations. Such protection was also excluded experimentally by homogenizing and fractionating cells 3 hr. after infection with virus and then incubating each fraction with 5 μgm./ml. ribonuclease for 30 min. at room temperature. RNA was extracted from the fractions using cold phenol and titrated in mice (Table 3). No significant change in the infectivity of RNA from any fraction could be detected following enzyme treatment.

Table 3. RESISTANCE OF FRACTIONS OF INFECTED CELLS TO RIBONUCLEASE

RNA preparation from :	Infectivity of RNA (LD_{50}/ml.) Untreated control	Ribonuclease treated
Whole cells	501	1,000
Nuclei	39·8	39·4
Mitochondria	42·2	39·8
Microsomes + sap	14·7	28·8

Cells were infected with 4 plaque-forming units/cell of murine encephalomyocarditis virus, incubated for 3 hr. at 37° C., lysed by osmotic stock (Martin, E. M., Coote, J., and Work, T. S., unpublished work), homogenized, and fractionated by centrifugation. A sample of each fraction was incubated with 5 μgm./ml. crystalline ribonuclease for 30 min. at room temperature. RNA was prepared from treated and control samples and tested for infectivity.

The resistance of the RNA component to ribonuclease can be partly overcome by preliminary incubation with a proteolytic enzyme, papain (Table 4). When the 10,000g deposit of lysed-infected cells (nuclei and mitochondria, containing most of the RNA component 3 hr. after infection[3]) was exposed to papain concentrations up to 10 μgm./ml., the RNA which could be extracted was not rendered less infective. However, ribonuclease treatment following the papain reduced the infectivity of RNA by one logarithmic unit. RNA extracted from fractions treated with 100 μgm./ml. papain followed by 5 μgm./ml. ribonuclease totally lacked infectivity; but this concentration of papain by itself considerably reduced the amount of infective RNA which could be recovered. Thus it would seem that the RNA component contains a protein which is combined in such a way that it is susceptible to the action of papain, but normally protects the RNA from the action of ribonuclease.

Table 4. EFFECT OF PAPAIN AND RIBONUCLEASE ON THE RNA COMPONENT

Papain concentration (μgm.)	Infectivity of RNA (LD_{50}/ml.) Untreated control	Treated with ribonuclease
0	4,200	—
1	4,200	68
5	6,800	680
10	4,900	68
100	19	0

Cells were lysed by osmotic shock 3 hr. after infection with 4 plaque-forming units/cell of murine encephalomyocarditis virus. The lysate was centrifuged at 10,000g for 15 min. and the deposit was suspended in cysteine–versene-citrate buffer pH 7·5. Papain was added to give the concentrations shown and the samples were incubated at 37° C. for 30 min. The pH was then adjusted to 8·0 and ribonuclease was added to a sample to give a concentration of 5 μgm./ml.; an untreated sample served as a control. After 30 min. at room temperature, the samples were frozen. RNA was extracted and tested for infectivity.

The RNA component in cells infected with murine encephalomyocarditis, therefore, probably consists of ribonucleoprotein particles, which represent the 'vegetative' form in which the virus is present during the eclipse phase. These ribonucleoprotein particles are smaller or less dense than the virus[1], or the microsomes of the infected cell, and we propose to call them 'virosomes' by analogy with ribosomes. RNA extracted from virosomes is infective, but since little plaque-forming material can be recovered from infected cells during the time when large numbers of virosomes are present, the particles themselves may have a low probability of initiating infection.

Franklin, Wecker and Henry[4] also showed that ribonuclease treatment (10 μgm./ml.) of a homogenate of mouse brain infected with mouse encephalomyelitis virus did not reduce the infectivity of the RNA afterwards extracted by phenol at 4° C. They concluded that the sole source of infective RNA from infected tissues was the virus particle, based on the fact that infective RNA could be obtained from purified virus using hot phenol and the assumption that only the virus particle is resistant to ribonuclease. Our results, however, suggest that some virus precursors may be resistant to ribonuclease. Moreover, theoretical difficulties occur if their conclusions are extended to other viruses which, like murine encephalomyocarditis, lack a stage sensitive to ribonuclease in multiplication. If RNA becomes infective only after incorporation into mature virus, it should be impossible to extract infective RNA from infected cells before mature virus particles are present. Since there is an increase in the quantity of infective RNA extracted during the first four hours after infection with murine encephalomyocarditis virus, it would, therefore, be necessary to postulate an increase in the number of mature infectious particles present during this time, and one would expect that this increase would be detectable by other means. There is good experimental evidence that a true eclipse phase occurs in the multiplication of murine encephalomyocarditis virus[5] and that the source of infective RNA is not the virus particle[1].

The eclipse phase, infectivity of extracted RNA and ribonuclease resistance of 'vegetative' virus, can be reconciled by the concept of the virosome. The infectivity of virus is then a property of its RNA, but in the infected cell this is present during the eclipse phase in small ribonucleoprotein particles, virosomes. The function of the virosomal protein is unknown; it may be involved in synthesis of virosomal RNA or simply be required to protect or stabilize the RNA. This protein presumably lacks the specific surface structure, which, in the mature virus particle, is necessary for adsorption or penetration of the cell, while the ribonucleoprotein particle may be too large to be taken up like a molecule of RNA; in this case, the virosome would not be infective and an eclipse phase would be observed. After eclipse, the virosome is coated with surface protein and acquires the properties of the infective particle. This extra protein may also make the particle more resistant to phenol extraction, so that it is necessary to use hot phenol to obtain an equivalent yield of infective RNA.

In the case of viruses with a ribonuclease-sensitive stage in multiplication[6], the RNA in the 'vegetative' state may be either bound or free, since some ribonucleoproteins are sensitive to the action of ribonuclease[7]. If these ribonuclease-sensitive materials were shown by some other means to consist of easily dissociated ribonucleoprotein particles, they too could be called virosomes, providing they contained infective RNA but themselves had a low probability of initiating infection. In the test for infectivity of ribonucleoprotein particles, it would be essential to exclude that due to spontaneously liberated RNA. Therefore, virosomes may not be confined to virus systems without a ribonuclease-sensitive stage in multiplication.

HÆMOGLOBIN F: ITS SIGNIFICANCE IN THE GENETICS AND EVOLUTION OF HÆMOGLOBIN

By DR. WOLF W. ZUELZER and ABNER R. ROBINSON
The Child Research Center of Michigan, Detroit, Michigan

THE recent hypothesis of Ingram and Stretton[1] visualizes the thalassæmias as true hæmoglobinopathies characterized by amino-acid substitutions in either the α- or the β-chain of the hæmoglobin molecule, which remain electrophoretically 'silent' because they do not alter the net electric charge but manifest themselves by depressing the rate of synthesis of hæmoglobin. The theory covers the genetic mechanisms controlling the structure and production of α- and β-chains and thus of the major adult hæmoglobins, but does not specifically account for the γ-chains of fœtal hæmoglobin, for the occurrence of which under normal and pathological conditions no satisfactory genetic hypothesis has yet been offered.

We wish to extend the speculation so as to account for the formation of hæmoglobin F and to present a unifying concept which relates the biochemical and genetic facts concerning hæmoglobin synthesis in the course of normal development as well as in the thalassæmias and the hæmoglobinopathies to basic control by the two pairs of genes known at present as α- and β-genes. Our thesis is that the production of γ-chains is under the control of the same pair of genes which determines the formation of β-chains, once the maturation of the fœtus has reached the point where adult hæmoglobin can be made. We are aware that this concept involves seemingly radical departures from present notions concerning the effects of the genetic coding mechanism on protein synthesis. On the other hand, the hypothesis seems capable of reconciling an extraordinary number of as yet poorly explained observations of diverse nature, clinical, hæmatological, biochemical, genetic and evolutionary, which form a body of evidence no fundamental theory can ignore.

The concept arose from the study of Caucasian pedigrees in which two distinct thalassæmia genes could be identified in heterozygotes by their divergent effects on the minor components hæmoglobins A_2 and F (ref. 2). One gene produced the now familiar pattern of an elevated A_2 fraction[3] with normal or barely elevated values for hæmoglobin F, the other was consistently associated with normal values for A_2 but exceptionally high levels of hæmoglobin F, ranging from 4 to 12 per cent. The presence of the two variant genes in one person had resulted in the classical picture of homozygosity, Cooley's anæmia, that is, the genes 'interacted'.

It is now known that both hæmoglobins A_2 and F possess α-chains[4,5]. The elevation of either component in a thalassæmic heterozygote thus militates against a depression of α-chain formation and indicates that both thalassæmia variants observed by us were of the β-variety, involving substitutions in a β-chain. The difference between hæmoglobins F and A_2 resides in the polypeptides complementary to the α-chains, the former possessing γ-chains whereas the latter has now been shown to contain so-called δ-chains[4]. Since the primary effect of β-genes should be limited to substitution and depression of synthesis of β-chains proper, the question arose how in these β-thalassæmias the variant β-genes could mediate differentially another effect, namely, the elevation of a γ-compound in one case and a δ-compound in the other. Clearly a simple compensatory mechanism involving independent effects of hypothetical γ- or δ-genes was not adequate.

The simplest possible assumption seemed to be that the character or site of the substitution in the β-chain itself determined the nature of the by-product, γ or δ, accumulating in consequence of a 'block' in the metabolic pathway of β-chain synthesis. Depending on the nature of the block caused by one or the other substitution, one or the other alternate pathway was being utilized and the resultant γ- or δ-chains (that is, potential β-chains which failed to achieve normal structure) combined with available α-chains to form either hæmoglobins F or A_2. The two thalassæmia genes might accordingly be written $\beta^{X\gamma}$ (or β^{XF}) and $\beta^{X\delta}$ (or β^{XA_2}) to characterize the two substitutions.

In this view, γ- and δ-chains become primitive or altered β-chains, the production of which would thus be controlled by β-genes. Regarded as primitive β-chains, the γ-chains of the alkali-resistant hæmoglobin F of the fœtus should then also be controlled by the genes which in later life determine the production of β-chains. On this hypothesis, the 'switch-over, from hæmoglobin *F* to hæmoglobin A in the normal fœtus can be viewed as a modulation of a single genetic effect, induced in the course of maturation, an event for which many precedents are known in the behaviour of enzymes and hormones. At a given point in ontogeny a previously inactive enzyme may become active, opening up a new metabolic pathway, and the same gene which earlier induces synthesis of γ-chains now expresses its complete structure and induces β-chain formation.

The implication that γ- and β- (as well as δ-) chains have large parts of their structure in common is in keeping with the results of 'fingerprinting' and amino-acid analyses of human hæmoglobins[6]. The further implication that a common pathway is utilized in the synthesis of ultimately divergent products requires the assumption that protein molecules can be assembled in a step-wise manner, a possibility not yet excluded by the known facts concerning the template action of the genic substrate DNA. This assumption is not necessarily in conflict with the basic concept of fixed genetic templates. It merely stipulates that the same complement of genetic material present in the fertilized ovum as in the fully developed individual may exert different effects under different conditions of internal or external environment.

The consequences of this hypothesis as applied to normal and abnormal human hæmoglobin synthesis can now be examined.

If γ-chains represent an early and β-chains a later expression of the activity of β-genes, it becomes possible to visualize how the same erythrocytes can contain both hæmoglobins F and A. As the final metabolic system matures, β-chains can be made in cells already containing a complement of 'primitive β', that is, γ-chains. Increasingly the production of newly synthesized hæmoglobin will entail the use of the ultimate pathway. The gradations observed in the acid-resistant staining of hæmoglobin of neonatal erythrocytes[7] correspond to the proportion of γ- and β-chains in each individual cell. The γ-pathway would seem to be a simpler one which always remains open. Synthesis of β-chains is relatively more complex, though once established it is the more efficient mechanism ; but a residual minimum of utilization of the γ-pathway always persists, hence the minute amount of hæmoglobin F in the normal adult.

It is more difficult to speculate on the biochemical and genetic basis for the production of the δ-chains of hæmoglobin A_2. Stated in a general way, our original observations indicate that primary control by β-genes influences the rate of production of δ-chains and possibly the activity of δ-genes if such exist. One might visualize the utilization of a common pathway which would permit the hypothetical δ-genes to complete manufacturing δ-chains only if the sequence of amino-acids up to the 'branching-off point' under the primary control of β-genes were normal, and one might then use the purely operational term, 'secondary genes', for δ-genes. For the purposes of our main hypothesis pertaining to the genetics of hæmoglobin F and its evolutionary meaning, it is immaterial whether such a relationship or one of several alternatives is assumed. The crucial point remains the actual observation that certain substitutions in a β-chain appear somehow to regulate the production of both γ- and δ-chains.

The assumption that the formation of γ-chains utilizes a simpler pathway than that of β-chains can be interpreted in terms of evolutionary theory. The alkali-resistant adult hæmoglobin of lower animals may be indicative of a γ-chain component reflecting an earlier evolutionary stage, and the final development of a β-chain type of hæmoglobin may represent a relatively late achievement of higher species brought about by a mutation of a 'γ-gene' to a 'β-gene'. If this were true, the transient occurrence of a γ-chain type, hæmoglobin F, in the human fœtus would be truly part of the recapitulation of phylogeny. An even more speculative possibility is suggested by the ontogenetic stability of the α-chains, which may be a still older evolutionary species of polypeptides utilized for hæmoglobin formation. The development of the γ–β type might then represent itself a mutation of an original α-gene, and one is tempted to coin the terms palæo-, meso- and neo-hæmoglobins.

As visualized by Ingram and Stretton, the many amino-acid substitutions theoretically possible in either the α- or the β-chain of the hæmoglobin molecule allow for many variants of either type of thalassæmia. The substitution may be more drastic than those leading to a mere increase of γ- or δ-residues and may result in the production of identifiably anomalous compounds such as hæmoglobin Lepore[8], which appears to be the expression of still another β-thalassæmia gene. It is of interest that in thalassæmic heterozygotes with hæmoglobin Lepore, as in the heterozygotes with the $\beta^{X\gamma}$ type of gene observed by us, the A_2 fraction was not increased, suggesting that this particular block likewise could not be associated with increased utilization of the normal δ-pathway. The combination of the Lepore trait with an 'ordinary' thalassæmia gene of type $\beta^{X\delta}$ resulted in thalassæmia major, as might be expected in an individual lacking the genetic mechanism for the production of normal β-chains altogether.

It would appear that in the presence of a severe block in β-chain synthesis, γ-chains are most readily made, presumably because the pathway utilized for their production is always open—as if the block were 'distal' to the 'branching-off point'. Thus, hæmoglobin F accumulates in all situations in which there is severe interference with the synthesis of both β-chains, whether the gene combination produces two identical or merely similar substitutions $(\beta^{X\delta})_2$ ('classical' thalassæmia), $(\beta^{X\gamma}\beta^{X\delta})$ (the homozygote observed by us), $(\beta^{X\delta}\beta^{X\,Lepore})$ (Lepore-thalassæmia), and probably in other variants yet to be found. The large concentrations of hæmoglobin F in thalassæmic homozygotes as well as the great individual variations reported from case to case (20–90 per cent) become understandable when viewed as the result of blocks of varying severity in the synthesis of β-chains.

The genetic basis for the large amounts of hæmoglobin F found in carriers of the so-called 'High F' gene is obviously very different from that involved in thalassæmia. Such persons show no hæmatological abnormality but exhibit 20–40 per cent hæmoglobin F (ref. 9). The gene is transmitted in a simple Mendelian manner and appears to be allelic to the genes for hæmoglobin S, C (ref. 10) and others already known to represent β-chain mutations[1]. The high percentage of hæmoglobin F presumably reflects not secondary accumulation of γ-chains resulting from a block in the synthesis of an altered β-chain but a 'back mutation' of a β-gene, making it assume the more primitive DNA structure coding for γ-chains as postulated in the evolutionary theory above—a molecular atavism as it were. The existence of such a mutation does, in fact, strengthen the evolutionary hypothesis.

It now seems possible to grade the various substitutions in the β-chain on the basis of the severity of the resultant blocks. Evidently the thalassæmias represent the most drastic of the many possible substitutions, since γ- and/or δ-chains accumulate, at least to a small degree, even in the heterozygous state. Synthesis of hæmoglobin is so severely reduced that the individual erythrocytes cannot fill themselves with pigment and become hypochromic–microcytic. By contrast, the substitutions involved in the sickling mutation and in hæmoglobins C, E, G and F (when produced by the 'high F' gene) are less drastic, that is, they reduce the rate of synthesis of the abnormal β-chains to a lesser degree. No γ- or δ-chain residues accumulate and no hæmatological effects are observed in the simple heterozygous condition. However, the occurrence of target cells in some of these states suggests less-than-optimal filling of the erythrocytes with hæmoglobin, in keeping with the reduced proportion of the abnormal hæmoglobin as compared to hæmoglobin A in heterozygotes ; but the reduction in total cellular hæmoglobin synthesis is not great enough to lead to measurable microcytosis. Some substitutions may not appreciably affect the rate of synthesis.

One might thus construct a tentative 'map' of the polypeptide substitutions based on the relative severity of the resultant blocks (and not to be construed in any strict 'geographical' sense) as follows : $\beta^{X\gamma} \longrightarrow \beta^{X\,Lepore} \longrightarrow \beta^{X\delta} \longrightarrow \beta^{S}$, β^{E} and $\beta^{C} \longrightarrow \beta^{D}$, β^{F} and $\beta^{G} \longrightarrow \beta^{A}$.

Homozygosity should result in increased production of hæmoglobin F in proportion to the severity of the resultant block. The thalassæmias, representing the most drastic substitutions, show the highest proportion of hæmoglobin F. Thalassæmia major is also the severest of the clinical syndromes, with severe anæmia and hæmoglobin deficit within the red cells.

Homozygosity for the sickling gene is complicated by the catastrophic effects which the physical state of hæmoglobin S in deoxygenated cells can produce on the survival of erythrocytes. Here the additional stress created by the rapid rate of hæmolysis may enhance the effect of a mutation which, in terms of its primary effect on the rate of hæmoglobin synthesis, would appear to be relatively mild, judged from the heterozygous state. Thus the demands made on enzymatic processes for the synthesis of the abnormal β-chains may be inordinately great, and part of the available substrate is forced into the less demanding γ-pathway. This may explain the presence of variable and usually modest amounts of hæmoglobin F in homozygotes for the *S*-gene, and the absence of hæmoglobin F increases in homozygotes for the *C*-gene, which causes a substitution at exactly the same point in the molecule.

When a β-thalassæmia gene is combined with another β-chain mutant such as *S*, *C* or *E*, the affected individual is unable to make any normal β-chains. In such double heterozygotes, hæmoglobin F may be expected to accumulate to an extent determined by the nature of the substitutions. The interaction effect apparent in the high proportion of the abnormal hæmoglobin S, C or E in persons who possess only one gene for S, C or E reflects the fact that the thalassæmic substitution is much more drastic than any of the other mutations ; or, in other words, that the rate of synthesis of the thalassæmic β-chain is much more depressed than that of the β-chain carrying an S, C or E substitution. The relatively large increases in hæmoglobin F observed in all these interaction syndromes may thus be attributed chiefly to the drastic depression of that β-chain which carries the thalassæmic substitution and is channelled principally if not exclusively into the γ-pathway.

Combinations of two mutant β-genes other than thalassæmia and causing less severe substitution effects might be expected to result in smaller, if any, increases in hæmoglobin F and in less severe anæmias. Sickle cell–hæmoglobin C disease may serve as an example. No increases in hæmoglobin F seem to have been reported. The approximately equal proportions of hæmoglobin S and hæmoglobin C in this condition indicate the equivalence of the substitution effects caused by the *S* and *C* genes (as might perhaps be expected from the similarity of the mutations themselves).

In α-thalassæmias the production of hæmoglobin F—or for that matter of hæmoglobin A_2—should not be enhanced, since these compounds contain α-chains. In non-interacting combinations with sickling or hæmoglobin C genes, α-thalassæmia genes seem to be involved. The proportion of hæmoglobin S or C in such cases is no greater than expected in simple heterozygotes, the inheritance is non-allelic, the proportion of hæmoglobin F is not increased and the values for both hæmoglobin F and hæmoglobin A_2 in the thalassæmic relatives are low or at most normal[11]. Available space does not permit a discussion of the implications of our hypothesis for the group of α-thalassæmias. It may be pointed out, however, that the transient appearance of Bart's hæmoglobin, a γ-tetramere[12], followed by the appearance of hæmoglobin H, a β-tetramere[13], in H-thalassæmia, which has been designated on other grounds as an α-thalassæmia[14], is in keeping with the assumption that the same genes successively induce synthesis of γ- and β-chains.

Small elevations of hæmoglobin F have been observed in a variety of unrelated hæmatological conditions. In the light of the hypothesis presented, this phenomenon may be interpreted as the result of stress leading to maximal utilization of enzyme systems required for β-chain synthesis, with ultimate development of a deficit necessitating the increased use of the alternate (γ) pathway. Such a mechanism was invoked above in order to account for the relatively high concentrations of hæmoglobin F in sickling homozygotes as compared to homozygotes for hæmoglobin C or E genes.

The hypothesis presented here, though based on apparently crucial observations, extends speculatively to many assumptions. It is presented because it seems to fit most observations concerning the structure and genetics of human hæmoglobins and because it can be tested in a variety of ways, experimental and clinical.

This investigation was supported by U.S. Public Health grant A-2940 (C1) and the Children's Leukemia Foundation of Michigan.

COMPLEMENT-FIXING BLOOD GROUP ANTIBODIES WITH SPECIAL REFERENCE TO THE NATURE OF ANTI-Le^a

By DR. F. STRATTON

National Blood Transfusion Service, Roby Street, Manchester 1

CERTAIN blood group antibodies are complement fixing, that is, they unite with homologous red cells, complement is fixed and lysis may ensue. In many instances, however, lysis does not result but the aggregate gives a positive antiglobulin test; it is only when the antibody is in high concentration that lysis occurs.

Dacie *et al.*[1] showed that the antiglobulin reagent united not with the antibody but with absorbed complement. In this article E represents erythrocytes, A antibody, and C' complement. In the combination EAC', therefore, antiglobin serum unites with C'. Later, Mollison[2] showed that EA, although not lysed by human complement, were lysed by certain animal complements, for example, guinea pig, rabbit.

Blood group antibodies that are complement fixing are cold incomplete anti-H, anti-Lewis (anti-Le^a and anti-Le^b), anti-Jk^a and anti-Jk^b, some examples of anti-Fy^a and anti-K, and certain antibodies from cases of cold acquired hæmolytic anæmia; these latter have been studied[3,4] and found to be γ_1-globulins. Although cold incomplete anti-H is undoubtedly the commonest antibody, unfortunately, as Dacie[5] originally showed, it does not unite with the red cells in the absence of complement and it is impossible, therefore, to prepare EA alone. One of the most useful antibodies to work with is anti-Le^a and $Le(a+)$ erythrocytes, particularly since anti-Le^a is a fairly common antibody. The work described in this article was done using this system.

Stratton[6] showed that EA could be prepared using this system, and originally it was found that the sensitized EA gave a negative antiglobulin test. It was the combination EAC' which, as previously described, gave a positive antiglobulin test. It was also possible to prepare an eluate from EA which would unite with $Le(a+)$ cells producing more EA; these EA may not themselves give a positive antiglobulin test but would, nevertheless, react with C', forming EAC'. Antibody could not be eluted from EAC'.

The components of C' which are fixed when C' reacts with EA are shown in Table 1. $C'2$ is completely fixed; this, however, gives no clue as to the nature of the C' component on EAC' which unites with the antiglobulin serum. This problem was tackled by three groups of workers in somewhat different ways[7–9], but they all came to the same conclusion—the important component was $C'4$. Jenkins *et al.*[9] demonstrated that the active fraction of the antiglobulin serum was anti-β_1.

Table 1. Fixation of C' Components by EA

	$C'1$ (per cent)	$C'2$ (per cent)	$C'4$ (per cent)
Normal serum	100	100	100
Absorbed with normal cells (E)	93	80	80
Absorbed with EA	73	0	48

This is a valuable system for studying the action of complement on the sensitized cell EA, since in addition to lysis a new sensitive method is available for detecting the absorption of C' by EA, namely, the antiglobulin test. Le^a group specific polysaccharide (provided by Prof. W. T. J. Morgan) can be utilized in experiments on sensitized cells. Le^a substance when mixed with EA in a suitable concentration will prevent the treated EA fixing C'; but it has no effect on the reaction between EAC' and antiglobulin serum. This, among other things, is another means of determining C' fixation[10]. In this system the binding power of complement on the antigen–antibody combination can be demonstrated.

As a preliminary to further investigations on the effect of C' on antibody in EA it was decided to try to determine the nature of the antibody. Fudenberg, Kunkel and Franklin[11], in a study of high molecular weight antibodies, pointed out that 5–10 per cent of the total γ-globulin of normal serum consists of faster-moving $19S$ component of molecular weight about a million. The other 90–95 per cent consists of $7S$ of a molecular weight of 150,000. It is known that mobility and weight are not necessarily associated, but, for convenience, in this article the two groups are referred to as γ_1- and γ_2-globulins. These workers found certain antibodies belonged to the first, or γ_1-group, for example, often complete antibodies or agglutinins, and others, such as incomplete Rh antibodies, to the second group. The main difficulty in this work is that most anti-Le^a C' fixing antibodies are of low activity and the amount of serum protein present as antibody is probably very small indeed. Many of the normal physical methods applicable to their study cannot be used and indirect methods have been employed from which tentative conclusions are drawn.

Work involving electrophoresis of anti-Le^a antiserum on polyvinyl particle blocks[12] showed that antibody activity was present in the γ-globulin fraction of the serum. The euglobulin fraction of the serum (prepared at pH 6·4) in certain instances contained all the antibody activity. It was thought possible, therefore, that the antibody belonged to the γ_1-globulin group. Deutsch and Morton[13] showed that sulphydryl compounds, such as mercaptoethanol, dissociate macroglobulins, and Grubb[14] applied this to study the effect of this treatment on sera containing blood group antibodies. Using essentially similar methods anti-*Le*^{a} sera so treated would not make *EA* or *EAC′* when mixed with *Le*(a+) erythrocytes, even after the addition of *C′*. This is what would have been expected if the antibodies were heavy-weight γ-globulins.

Many different anti-*Le*^{a} antisera were used to prepare *EA*. All the examples of *EA* originally prepared were un-agglutinated by routine or commercial antiglobulin sera, or even by those prepared following immunization of rabbits with euglobulin fractions of normal human serum. Nevertheless, that such an antiglobulin serum was united with *EA* was suggested by its ability to impair or abolish human *C′* fixation by *EA* pre-treated with antiglobulin serum. Afterwards, potent anti-*Le*^{a} sera were found from which *EA* could be prepared which were agglutinated by anti-euglobulin antisera (Table 2).

Experiments were done involving the titration of sensitized cells *EA* with antiglobulin sera, together with tests of the inhibiting effect of γ_1- and γ_2-globulin preparations on the ability of anti-γ_1 serum to agglutinate sensitized cells. Prof. N. Martin provided anti-γ_1 and γ_1-globulin, and the γ_2-globulin preparation used was free from heavy component. *EA* were prepared using several different anti-*Le*^{a}, and the *Rh* sensitized cells were coated with antibody considered to be a γ_2-globulin (Tables 2 and 3). Additional tests[12] also showed that α- and β_1-globulins were non-inhibitory. Table 4 shows that there is a correlation between the titre of the antiglobulin serum with the *EA* and the extent of their lysis by absorbed guinea pig serum. This suggests that the differences of antiglobulin titre may be due to differing amounts of antibody on the *EA*. These results (Tables 2, 3 and 4) suggest that the antibody on *EA* is a γ_1-globulin.

Further experiments on the effect of *Le*^{a} substance and mercaptoethanol on the sensitized erythrocytes, *EA* themselves, provided additional information. If a 10 per cent suspension of *EA* (iii, Table 2) was mixed with an equal volume of 2×10^{-5} solution of *Le*^{a} substance at 37° C., the *EA* were not then agglutinated by the antiglobulin serum. Secondly, treatment of *EA* with 0·2 *M* mercaptoethanol at room temperature for 2 hr. resulted in a negative antiglobulin test and the titration score[15] fell from 15 to 0, but if *Rh*-sensitized cells were similarly treated the titration score was reduced only from 26 to 23. The mechanism of these effects is not entirely clear, but it does suggest that normally the antiglobulin serum is united with the absorbed antibody. This is important because it is possible that serum proteins, other than antibody, may be absorbed on to *EA* at the time of their preparation (cf. Vaughan[16]). The second group of experiments will be more fully described elsewhere.

In reaching the conclusion that these *C′* fixing anti-*Le*^{a} antibodies are heavy-weight γ-globulins, it must be borne in mind that the γ_1-globulins used in inhibition tests and for the preparation of antibodies are from cases of macroglobulinæmia and, therefore, are pathological and not normal serum proteins.

Table 2. TITRE OF ANTIGLOBULIN SERA WITH VARIOUS SENSITIZED CELLS

Test cells*	Antiglobulin titre Anti-euglobulin	Anti-γ_1
EA i	0	16
ii	1	16
iii	8	128
iv	16	512
Rh-sensitized cells	64	1,024

* *EA* prepared with different anti-*Le*^{a} i–iv.

Table 3. INHIBITION TESTS

A Substances added to equal vol. of anti-γ_1 dil. 1/20	*B* Antiglobulin test mixtures from column *A* *EA* (iv)*	*Rh*-sens.*
Saline	+ + + + +	+ + + + +
γ_1-Globulin dil. 1/400	Neg.	+ + + + +
γ_2-Globulin dil. 1/25,000	+ + + + +	Neg.
γ_2-Globulin dil. 1/1,000	+ + + +	Neg.
γ_2-Globulin dil. 1/100	Neg.	Neg.

* As in Table 2.

Table 4. RELATIONSHIP BETWEEN ANTIGLOBULIN TITRE AND LYSIS OF *EA*

Test cells*	Antiglobulin test titre	Lysis with absorbed guinea pig serum (per cent)
EA i	0	0
ii	2	0
iii	8	40
iv	16	70
E	0	0

* As in Table 2.

Practical applications of these observations spring to mind. An antibody, anti-γ_1, active against the antibody is available, together with another, anti-β_1 (ref. 9), against absorbed complement; these facilitate the study of the action of *C′* on *EA* (ref. 10). Wiener *et al.*[17] have used a system involving the neutralization of antiglobulin serum for the detection of human serum globulins. The results shown in Table 3 may be taken to illustrate the known cross-reactions between γ_1- and γ_2-globulins or their impurity. Purified protein preparations prepared by chemical methods must always be regarded as impure when considered for immunological work and, similarly, an antibody prepared in animals is not merely an antibody against a single protein but also contains a spectrum of antibodies. Thus far, the system has been used only for the assessment of the relative purity of serum fractions supposedly predominantly either γ_1- or γ_2-globulin.

EFFECTS OF IONIZING RADIATIONS ON RICE PLANTS

By MAUNG MYA THAUNG

Department of Agriculture and Biology, Union of Burma Atomic Energy Centre, Yankin P.O., Rangoon, Burma

THE effects of ionizing radiations on various plants have been reported by many investigators since the early work of Stadler[1,2]. Hence, there exists a wealth of information on the radiophytological responses. The results of plant reactions during the first year of study on radiation induction of useful mutations in a rice crop are presented here and discussed with the view of enlarging our present knowledge of radiobiological effects.

Five varieties of Burmese rice (*Oryza sativa* var. *indica*)—*A*36–3, *B*401, *C*28–16, *D*25–4 and *Xq*–4—were each irradiated both with 25 kr. and 35 kr. of X-rays at the Brookhaven National Laboratory, after exposure to a relative humidity of approximately 60 per cent for about 2 weeks. Nearly 3 weeks after this processing, some of the irradiated seeds were germinated here on moist filter-papers in Petri dishes on May 11, that is, about one month in advance of normal sowing season which usually falls due in mid-June. The remaining lot set aside at room temperature was likewise sprouted on June 15 to study the storage effect, if any.

The sprouts were transferred from dishes to earthen pots during 3–6 days following germination. Water was supplied regularly and close observations were made daily. All were uprooted, measured, photographed, and transplanted in pots when about 32 days old. Seedling fatality was expressed as the number of dead seedlings (per cent of germinants).

Tillerings and heights of transplants were recorded weekly. About 2 weeks before floral emergence, both treated and untreated transplants were properly isolated in linen bags in case of cross-pollination in the irradiated (*R*1) generation. This preventive measure was necessary to ensure that mutants to be screened in generation *R*2 were due to radiation only. Seed fertility was determined by counting the total number of both filled and unfilled grains in each treatment, and then calculating the number of filled grains per hundred of that total number. The susceptibility value of rice plants to false smut disease due to *Ustilaginoidea virens* (Cke.) Tak. was computed as the number of infected grains as a percentage of all filled grains in the treatment.

Four other varieties of Burmese rice—*A*28–81, *B*24–92, *C*33–18 and *D*17–88—after bombardment with thermal neutron fluxes of $6{\cdot}92 \times 10^{8}$/cm.^{2}/sec. and $6{\cdot}70 \times 10^{8}$/cm.^{2}/sec. for 15 and 20 hr., respectively, on July 13 at Brookhaven were germinated, as described, on August 12. Transplantation was completed on September 14, and transplants in the neutron-treated (*N*1) generation were also isolated.

As shown in Table 1, there was practically no difference in germination of rice grains either among varieties or treatments with X-rays or thermal neutrons. On the other hand, Mashima and Kawai[3] reported a decrease in germination-rate of rice grains as a result of exposure to both X-rays and thermal neutrons. Development of sprouting seeds apparently slowed down directly the X-ray dosages increased. During the initial stages of growth in the nurseries, *R*1 seedlings looked like lean, medium-dwarfs with relatively thick, narrow, and dark green leaves, displaying varying degrees of foliar convolution and restricted growth. Only one albina-type mutant showed up among sixty-three 25-kr. members of *B*401, but it did not survive transplantation. Other such chlorophyll-defective mutants as those with chlorotic/yellowish stripes along margins or mid-ribs of leaves were seen on two *C*28–16, two *D*25–4, and one *Xq*–4 members of the 25-kr. treatment.

Fatality and retardation in height of 32-day old rice seedlings generally increased as the X-ray dosages increased (Table 1). Some differences of intervarietal responses were also apparent. Matsuo *et al.*[4] made similar observations on mortality and inhibition of seedling height. However, *B*401 seedlings were taller at a higher dose-rate than at the lower dose-rate. Such an apparent stimulation at a higher dose-rate, and a direct relationship between chronic gamma-ray dosage and degree of growth inhibition in *Vicia faba* were also reported by Sparrow and Gunkel[5]. Ouang and Chang[6] recorded about 10 per cent increase over the control in height of *X*1 (*R*1) plants. A departure from direct proportionality between reduction in height of maize seedling and radiation doses at certain dosages of X-rays or thermal neutrons had been demonstrated by Schwartz[7], though. Moutschen[8] noted the same with barley coleoptiles, the develop-

Table 1. RICE GRAIN GERMINATION, SEEDLING FATALITY, SEEDLING HEIGHT, AND RANGE OF SEEDLING HEIGHTS IN *R*1 AND *N*1 GENERATIONS RAISED ON MAY 11, 1959

kr., kiloroentgens of X-rays ; hr., hours of exposure to thermal neutrons ment of which depends on both cell-division and cell-elongation. According to Schwartz and Bay[9], seedling growth is determined simultaneously by mitotic inhibition and intensity of chromosomal damage.

As observed by Ehrenberg and Nybom[10] and Caldecott[11] in barley, and Matsuo *et al.*[4] and Yamaguchi[12] in rice, both wide and narrow ranges of seedling heights were obtained ; this suggested larger and smaller deviations around mean values in the X-ray and thermal neutron treatments (Table 1), respectively. Contrary to the results of Matsuo *et al.*[4] and Huang[13] on the progressive inhibition of seedling height consequent on increasing bombardment with thermal neutrons, Table 1 indicates no appreciable disparity in height among the treatments.

Table 2 suggests that about one-month delay in sowing clearly enhanced the fatality of seedlings from grains irradiated with X-rays, but did not apparently affect germination of almost all strains tested. The storage effect, as it is termed, was also exhibited in barley seeds, and depended on a number of factors (Caldecott[14]).

Differences in height among treatments may persist in transplants of certain varieties for some weeks. Later these may narrow down close enough to suggest a recovery from the setback in growth at the early stages. Success in attaining the height of the control at the time of flowering of *R*1 wheat plants was also observed by Bora[15]. The stunting effects of X-rays are probably due to gene mutation[6].

Tillering in some strains may vary directly or inversely with the X-ray doses. Yet, most of the tillers in the treated plants were either late or poorly developed and unproductive. The early differences in the numbers of tillers between treatments tended to drop and the number became nearly equal to the control later in the season owing mainly to the death of underdeveloped tillers in certain strains. Natarajan *et al.*[16] and Bora[15] obtained a decrease as well as an increase in the number of tillers in wheat plants, respectively, whereas Ouang and Chang[6] reported both inhibitory and stimulatory effects of X-rays on tillering in rice plants.

Table 3 summarizes the number of panicles per plant, grains per panicle, and percentages of grain fertility and susceptibility to false smut disease, and dates of heading. There was a significant gain in the number of panicles per plant at 35-kr. dose-rate as compared to controls; the exceptions are probably irresponsive *B*401, highly responsive *C*28–16, and adversely affected *Xq*–4 at both levels of X-rays, while such a difference between controls and 25-kr. treatments was mostly lacking ; but nevertheless, the panicles of *R*1 plants usually had less grains than those of their respective controls. Essentially, no considerable divergence in grain or panicle numbers was apparent among the thermal neutron treatments. Grain fertility was greatly reduced though not always in progression with the dosages administered. Ouang and Chang[6] and Matsuo[4], however, found a direct relation between the grain sterility and the dosages. As reported[13], the depression of grain fertility seemed to be more severe in thermal neutron than in X-ray treatments. Grain sterility is attributed to chromosomal damage or rearrangement[17,18]. The resistance to false smut disease of all varieties studied remained almost unimpaired at the levels of X-rays used. Most of the *R*1 plants of 25-kr. series came to heading 2–5 days later than the controls. Ouang and Chang[6] noticed earliness as well as lateness in heading of treated rice plants while Huang[13] reported a distinct delay in flowering.

GEOPHYSICS

Origin of Stone and Iron Meteorites

THE question arises whether meteorites in general have had a common origin, and in particular whether the stone meteorites have had an origin different from that of the iron meteorites. One line of experimentation bearing on this problem is the determination of cosmic-ray exposure ages of meteorites. If the total content of a stable cosmogenic nuclide is measured, and if its rate of production can be determined, then the length of exposure to the radiation is known.

But the rate of production of a stable nuclide must be estimated either from purely theoretical considerations or from measurements on a radioactive nuclide. The theoretical arguments are probably not too reliable at this stage, and the best estimates seem to be based on radioactivity measurements. For example, the tritium decay-rate at the meteorite's time of fall gives directly the tritium production-rate, and if the cross-section ratio $\sigma_t/\sigma_{^3\mathrm{He}}$ is known, the helium-3 production-rate can be calculated. Then from measured amounts of helium-3 an age can be determined.

A table of such meteorite ages has recently been compiled by Urey[1]. The helium-3 measurements were carried out by a number of investigators, using either mass spectrometry or activation analysis. The production-rate was calculated on the basis of five tritium measurements in different stone meteorites. Since all the values were approximately equal, it was concluded that the helium-3 production-rate is invariant and equal to 10^{-8} stand. c.c./gm./million years. The production in iron meteorites was chosen as half this value.

These calculations lead to a general trend of ages, as shown in Fig. 1. A discrepancy can be seen to exist between the ages of the stone meteorites and those of the iron meteorites. On this basis it was suggested[1] that the stones and the irons may have had a different origin and history. The irons presumably coming from the asteroidal belt, perhaps the stones come from the surface of the Moon. This would be in line with shorter exposure ages for the stones.

But several refinements which should be made to such an estimation of exposure ages lead to perhaps not negligible adjustments. In particular, one should try to estimate better the difference in helium production-rates in iron and stone meteorites, the dependence on depth of helium production, and the effect of space erosion. Some preliminary experimentation has been done on at least the first two of these effects.

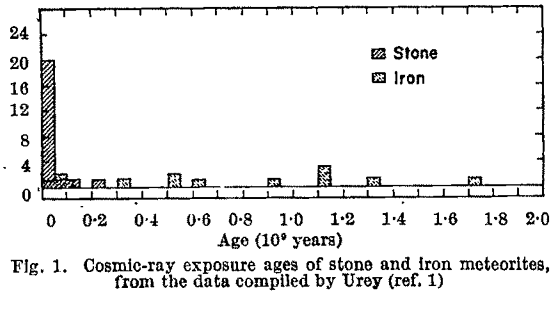

Fig. 1. Cosmic-ray exposure ages of stone and iron meteorites, from the data compiled by Urey (ref. 1)

Aluminium may be considered to be an element of Z nearly equal to the average for stone meteorites, and $\sigma_{^3\mathrm{He}}$ for an iron target has been found to be greater than for an aluminium target[2], increasing to a factor of three at bombarding energies of several BeV. (Schaeffer, O. A., and Fisher, D. E., unpublished results). When one applies this correction to Urey's data, and when data on seven other iron meteorites that have been recently measured[3] are included, the discrepancy in ages between the stones and the irons is largely removed. However, more cross-section data are needed for those elements which actually make up the bulk of stone meteorites.

It is not clear whether the dependence on depth of nuclide production will be important in stone meteorites, although in irons it has been shown[4] that a production-rate taking this factor into account may vary by up to an order of magnitude from estimations ignoring the effect. Eberhardt and Hess[5] assume that the effect will be negligible in stones, because of their rather small size. But many of the stones are of size comparable to several irons in which a serious depth effect has been estimated. Further, Öpik has pointed out that stone meteorites have a high probability of shattering on contact with the Earth's atmosphere, so that small fragments found on the Earth may actually have been in a large meteorite in space[6]. If a depth-effect exists, one would expect to find differences in content of both stable and radioactive nuclides within the same meteorite, and differences in content of radioactive nuclides in different meteorites, such as are found in irons. Begemann *et al.*[7] found the same tritium content in two pieces of Norton County stone meteorite, but Fireman and DeFelice[8] found a value half as much in still another piece. Fireman and DeFelice also measured the argon-39 in two pieces of Norton County and found a 30 per cent variation. Eberhardt and Hess[5] measured the helium-3 in four stone meteorites that have been investigated by other workers, and in three of them obtained significantly different values, two of them differing by greater than a factor of ten. Some recent tritium measurements in different stone meteorites suggest a range of values[9]. The argon-39 contents of two stone meteorites were measured[8] and a factor of four difference was found. From these considerations, then, it would appear that a serious dependence on depth may exist in stones.

A scheme for estimating the depth-dependent production-rate of stable nuclides in iron meteorites, based on argon-39, chlorine-36, and rare gas ratio measurements, has been presented[3,4]. It is not so easy, however, to estimate this effect in individual stone meteorites. The rare gas ratios are not expected to vary uniformly with depth, due to radiogenic helium-4 and to a varying chemical composition which will affect neon and argon production. Approximations to the upper and lower limit of helium-3 production-rates in stones can be estimated,

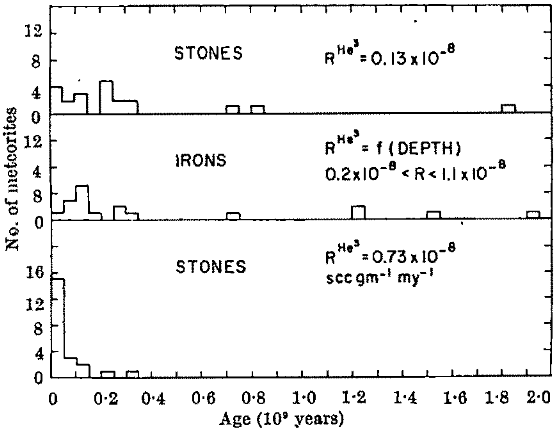

Fig. 2. Depth-dependent cosmic ray exposure ages for stone and iron meteorites. $R^{3\text{He}}$ = helium-3 production-rate in standard c.c./gm. of meteorite per million years

however, from the upper and lower limits in the iron meteorites[4] and from the relative cross-sections in iron and aluminium targets. The ages thus calculated are shown in Fig. 2. In this figure ages have been calculated only for those iron meteorites for which all the rare gases have been determined. A production-rate in stones of $0{\cdot}7 \times 10^{-8}$ stand. c.c./gm./m.y. may be compared to that of $1{\cdot}0 \times 10^{-8}$ obtained by Urey on the basis of tritium measurements. Ages have also been calculated[3] for the irons on the basis of their neon-21 and argon-38 contents, and on measured values for the ratios $\sigma_{^3\text{He}}/\sigma_{^{21}\text{Ne}}$ and $\sigma_{^3\text{He}}/\sigma_{^{38}\text{Ar}}$ in iron targets. These ages agree well with the helium-3 ages.

The age distribution for the stone meteorites, with $R^{3\text{He}} = 0{\cdot}7 \times 10^{-8}$ peak at a lower value than does the iron age distribution. There are several stones with ages of approximately 10–20 million years, and none older than 400 million years, whereas some irons are older than a billion years. However, when $R^{3\text{He}}$ reaches $0{\cdot}13 \times 10^{-8}$ in stones, the stone age distribution is no longer different from the iron's. As the depth effect becomes more important in stones, then, their age distribution shifts more towards that of the irons. It should also be noted that a slightly younger age for the stone meteorites is reconcilable with a longer mean life against collision destruction in the asteroidal belt for irons than for stones. From Fig. 2 it does not seem possible to say that there is an age difference greater than can be accounted for by this consideration.

Only a very general statement can be made at this time on the effect of space erosion. However, it should be expected that the combined wearing effect of dust, gas, ions, and electrons in interplanetary space might be quite different for irons than for stones. Fireman and DeFelice[8] have shown that the effect may be quite large, and may be more than two orders of magnitude greater for the softer stones than for irons. This would lead to a shorter apparent age for the stones.

Until more information is forthcoming, then, on more direct radioactive-stable nuclide determinations (such as argon-38/argon-39, as well as hydrogen-3/helium-3), one is not justified in postulating separate origins for the stone and iron meteorites on the basis of their cosmic-ray exposure ages.

I am grateful to Dr. O. A. Schaeffer of Brookhaven National Laboratory for his criticism. Part of this work was done while I was at Brookhaven National Laboratory.

Enhancement of Night-Sky Molecular Nitrogen Emission in Polar Cap Absorption Events

IT has long been accepted that auroral activity is associated with magnetic disturbances. Observations inside the auroral zone show the relationship to be rather complex; bright auroral displays are often observed during quiet magnetic conditions, and even in the greatest of magnetic storms visual auroræ are not always observed. On the other hand, well-exposed auroral spectra are always obtained during these storms. The source of this emission lies in extensive glows, often above the threshold of vision, but of such low contrast that observers normally do not recognize or report them. Changes in the colour of the night sky can be observed on colour film exposed during such storms. The forbidden atomic oxygen lines and the first negative, first positive and second positive bands of molecular nitrogen are all enhanced in these glows.

Since the beginning of the International Geophysical Year, patrol spectrographs have monitored the night sky emissions in the Antarctic and Arctic. The zenith intensity of the first negative band of ionized molecular nitrogen at 3914 Å. has been determined during some of the major magnetic storms, at stations situated inside the auroral zone.

The relative intensity of the band at 3914 Å. is plotted on a logarithmic scale in Fig. 1. Curve 1*a* is the intensity variation during May 1959, at South Pole Station, Antarctica, and curve 1*b* is the intensity variation during November 1960, at Thule, Greenland. On May 10, 1959, a flare on the Sun was followed about 6 hr. later by the start of a polar cap absorption event. Soon after the polar cap absorption began, the intensity at 3914 Å. began to increase steadily, reaching a maximum, some 100 times above normal minimum night-time levels, about 24 hr. later, coincident with the peak of activity of the associated major magnetic storm. The intensity then fell steadily, returning to its normal night-time minimum values some 48 hr. after the peak.

In November 1960, two similar events occurred following flares on the Sun, and the sequence of events at Thule is almost identical to the behaviour observed at South Pole Station in 1959. The times of the flares, polar cap absorption commencements and the sudden commencements of the magnetic storms are shown in Fig. 1.

The intensity of the first and second positive bands of molecular nitrogen show the same behaviour as the first negative bands.

In the three large polar cap absorption events, in July 1959, the same behaviour was observed at Scott Base, Antarctica. These observations cover six polar cap absorption events, indicating that this behaviour is not unusual.

Comparison with all-sky camera films shows that most of this energy does not arise from visual auroral forms, since, during many of the exposures at the height of the storms, no auroral forms could be seen in or near the zenith.

The onset of the increased nitrogen emission is closely associated with the beginning of the polar cap absorption. Throughout this absorption the *D*-region ion density is well above its normal level, which implies that a large flux of ionizing and exciting particles is penetrating down to heights of 65 km. and lower[1].

At Thule the observations begin and end when the Sun is illuminating the atmosphere down to 100 km. in the zenith. During normal days the emission at 3914 Å. shows considerable twilight enhancement (shown in Fig. 1*b* by dotted lines which are exposures during which the solar depression is less than 18°). During the great storm enhancements no twilight enhancement is evident, suggesting the emitting region is below 100 km. The storm enhancement is so great that the normal twilight enhancement at these times would not be apparent. At Pole Station, in Fig. 1*a*, the Sun is at a constant solar depression of approximately 18°, so no twilight effects occur.

The forbidden OI lines at 6300 and 5577 Å. do exhibit enhancements during the main phase of the magnetic storm, but they do not exhibit the steady changes over a period of days like the molecular nitrogen emissions. The Vegard–Kaplan bands of nitrogen are not observed in these spectra. These emissions are all from metastable states which would be collisionally deactivated below 100 km. The molecular oxygen bands are also present in the spectra. These factors suggest that the source of emission is near or below 100 km.

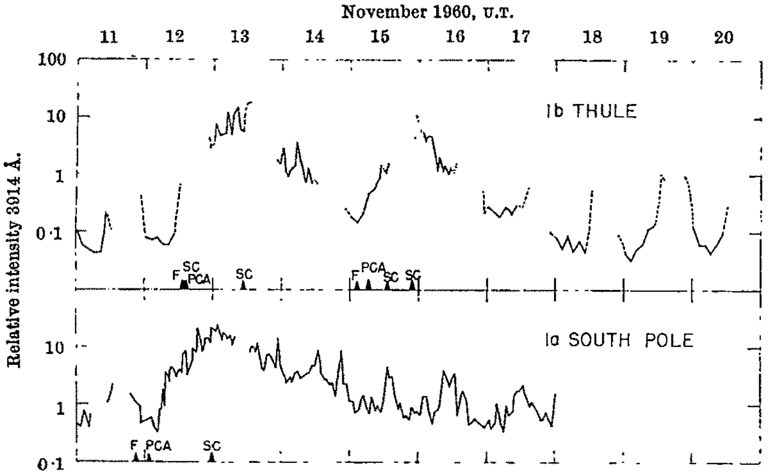

Fig. 1. The relative intensity in the zenith of 3914 Å. radiation at South Pole Station from May 10–16, 1959, in Fig. 1*a* and at Thule from November 11–20, 1960, in Fig. 1*b*. Times of major flares, polar cap absorption commencements and magnetic storm sudden commencements are indicated

ASTROPHYSICS

Origin of Cosmic Rays

ALTHOUGH cosmic rays have been known for more than forty years, their origin has not been satisfactorily elucidated. At present, it is believed that primary cosmic rays comprise nuclei of heavy elements ≈ 1 per cent apart from protons and α-particles. The presence of cosmically rare elements, for example, lithium, beryllium and boron in cosmic rays is of considerable importance for any theory of their origin. The other characteristic of cosmic rays is the energy spectrum which is of the form:

$$I(E) = KE^{-\gamma} \qquad (1)$$

where I is the intensity of a given kind of particles and E is the total energy of a proton or nucleon. Here γ varies between 1·9 and 3·0, depending on the energy range. Their energy lies between 5×10^{8} and 10^{18} eV. They also show in general the isotropy. The small anisotropy is, however, generated by the local sources and the local magnetic fields.

It is generally believed that the acceleration of ions in astronomical objects is caused by the interaction of the electric charge of ions with the local magnetic fields and not from nuclear or particle decay. Several acceleration mechanisms for the cosmic ray particle have been discussed in the literature, but none of them satisfactorily takes account of the whole range of the energy spectrum. I am of the opinion that not a single mechanism is involved, but a multiple process depending on the environment. Alfvén[1] has discussed the possibility of solar origin for the cosmic radiation. The theory is in good accord with most of the observed phenomenon, for example, the variations of cosmic rays in relation to various solar features, etc. However, it needs revision which has been deferred for future publication. On the other hand, Fermi[2] developed the theory of acceleration of cosmic dust through interstellar space. The cosmic particles are accelerated in interstellar space by moving magnetic fields. The longer the particle moves in interstellar magnetic fields, the greater will be its energy. From elementary considerations, he obtained the energy spectrum of the form of equation 1. However, this mechanism can accelerate only those particles the energy of which exceeds a minimal 'injection' energy (E_{inj}), which for protons in interstellar space is $\approx 10^8$ eV. and for iron nuclei, 5×10^9 eV./nucleon. Further, Alfvén's theory[1] cannot account for the particles of energy $> 10^{15}$ eV. Thus there must be some sources inside the galaxy which somehow generate particles of energy exceeding E_{inj}. The particles carrying great energies abandon their sources and are released into interstellar space, where they move in galactic magnetic fields for hundreds of millions of years and become accelerated by Fermi's mechanism.

The solar flare of February 23, 1956, is of considerable interest. During this flare, particles of the energy-range 10^9–$2{\cdot}4 \times 10^{10}$ eV. were observed. Simpson[3] found the total energy of the flare to be well in excess of 10^{32} ergs. These flares may be much more frequent in red dwarf stars as compared with the Sun and may in fact be the source of cosmic ray generation. In particular, the flare stars of spectral type *dM3e* (*UV* Ceti) and later, are very numerous. Perenago, as quoted by Shklovsky[4], believes that red emission dwarfs constitute a considerable fraction of the entire population of red dwarfs, the most abundant stars in the galaxy. It is possible that essentially all red emission dwarfs are flare stars to some extent. During the flare of *UV* Ceti stars, which lasts for several minutes, the luminosity rises by a factor of about ten. The flare occurs from once to several times a week. Thus the flare phenomenon on such stars is of the same general character as on the Sun, but will be much more energetic. Shklovsky[4] found that the power of optical radiation in a red-dwarf flare will be some 300 times as great as for such large solar flares as that of February 23, 1956. Thus the total energy of the red dwarf flare will be well in excess of 3×10^{35} ergs.

According to Kuiper[5], 81 per cent of the main sequence stars are *M*-dwarfs. The total number of stars of a galaxy are $\approx 2 \times 10^{11}$ and about 95 per cent of all the stars in our galaxy belong to the main sequence. Thus the total number of *M*-dwarfs in our galaxy will be $1{\cdot}6 \times 10^{11}$. Let us now assume that 10 per cent of the *M*-dwarfs are emission stars accompanied by a flare and that the flare event occurs on the average once in a year. The total release of energy by all the *M*-dwarf emission stars will be $\approx 1{\cdot}5 \times 10^{38}$ ergs/sec. This estimate may be an order of magnitude or two less because of the conservative approximation. Shklovsky[6] found that about 10^{39} ergs/sec. are lost in the galaxy as a result of nuclear collisions with interstellar gas. Thus I conclude that red dwarfs will supply sufficient energy to maintain dynamic equilibrium of cosmic rays in our galaxy. The hypothesis is further supported by the presence of heavy nuclei in cosmic rays since the synthesis of elements is advanced in the stellar system.

METEOROLOGY

Numerical Retracing of Atmospheric Events

For obvious practical reasons, all numerical integrations of the equations of atmospheric motion published so far have been made forward in time. To be useful, such numerical forecasts must be started from a position of uncertainty and extend up to, or beyond, the most clear-cut stage of the development in question. But the numerical approach can also be regarded as a method of experimenting with the atmosphere, and in that context the above procedure seems far from ideal. It would then be more logical to start from some well-defined point separating the initial and mature stages and to integrate forward and backward in time, possibly using different models for the two stages. Since the origins of atmospheric disturbances are often inconspicuous on the synoptic scale or obscured by lack of observations, the processes during the developing stage, and hence the results of the backward integration, would in general have the principal interest in this type of experimental work.

At first sight, a backward projection of atmospheric events seems to require the reversal of the large-scale flow—a major dynamical problem. However, the structure of numerical integration procedures offers a very simple means of reversing the direction of the time co-ordinate itself. All the procedures suggested so far make use of rates of changes, or 'tendencies', which are assumed constant during each time-step and are added to the values of the corresponding variables at time t to obtain their values at time $t + \Delta t$. A reversal of the time-direction therefore requires merely that the tendencies be subtracted instead of added.

Owing to the use of non-centred differences, the subtraction of tendencies will not ensure a complete reversal of events; but the discrepancies between the results of forward and backward integrations evidently arise from comparable errors in both computations. Other elements of irreversibility are introduced by finite difference approximations, smoothing operations and boundary processes.

The last of these require brief discussion. Charney, Fjørtoft, and von Neumann have shown[1] that conditions must be prescribed in detail for boundary points with inflow. Mathematical arguments were presented recently[2] in favour of relaxing this condition, but it seems likely[3] that the prerequisites for this are not generally fulfilled. Backward integrations can be expected to illuminate this point further, since the reversal of flow implied in the reversal of time should make it necessary to reverse also the boundary condition.

We have tested the arguments presented here by means of the barotropic model applied to 500-mb. charts for the Australian region. The first calculation took an existing situation 24 hr. forward in time and then brought it back to the starting point. There was a loss of minor details, but all major features were fully restored. Computational instability developed during the retracing calculation at the outflow boundary, and vanished when the boundary condition was reversed. This supports the validity of the classical argument[1], and was further confirmed by the second calculation.

In this a marked upper depression which had developed unexpectedly over western Bass Strait was traced backward for 24 hr. to a region of the Great Australian Bight, where the available observations could not have shown its existence. The calculation also indicated the presence of a depression over the southern Tasman Sea, where the analysis previously had shown only an indefinite trough.

These results suggest that the retracing of large-scale flow developments may also have practical utility. Even with the best of present-day networks, forecasts remain affected by the uncertainties of regions lacking observations. The backward integration procedure can be used to make the analysis in such regions dynamically consistent with that for the network area. This approach will be explored in detail when we test the performance of the barotropic and other models in the Australian region.

We are indebted to the Bureau of Meteorology for the 500-mb. charts used in this work, and to Dr. F. Loewe and Dr. F. A. Berson for helpful comments.

Small-Scale Turbulent Diffusion in the Atmosphere

Clarenburg and Tang[1] recently published a communication under this title in which they compared observations of smoke cloud spreading made by Frenkiel and Katz[2] with the relationships t, and $(t + 3)^{(2-n)/2}$, where t is time after generation of the burst, and n describes the shape of the one-point Lagrangian velocity autocorrelation; n was assigned the value 0·26, following Sutton[3]. Before the conclusion by these authors about the results of this comparison can be accepted, two points must be made:

(1) The authors base their computation of the spreading of smoke puffs on Sutton's well-known diffusion theory. It was pointed out in 1946, by M. I. Yudine[4], who referred to Richardson's[5] work and to the paper by Obukhov[6], that Sutton's treatment describes average dispersion, computed with reference to a fixed space-point or axis; but it does not describe relative diffusion of particles about a centre of gravity which is itself at liberty to move with the turbulence, as is the case with a smoke puff. The point has been emphasized and clarified in papers by Brier[7], and Batchelor[8–10], and many others. Relative diffusion depends on factors additional to the single-point, Lagrangian velocity correlation and hence cannot be described correctly by means of the parameter n. The additional factors governing relative diffusion are: (*a*) the initial size of the smoke puff; (b) multi-point Lagrangian correlations. Arguing from Obukhov's dimensional theory of turbulence, Batchelor deduced that the dispersion of a smoke puff should be proportional to a power of t less than unity at first, and afterwards to $t^{3/2}$.

(2) Clarenburg and Tang compared their diffusion theory with Frenkiel and Katz's excellent series of observations of the diameters of nineteen smoke puffs. The experiments were made on two successive days, and consisted of 7–20 photographic puff observations per experiment, made at one-second intervals. When a smoke puff spreads, at first its visible diameter increases; but later a maximum is reached, followed by a rapid decrease to zero. This maximum diameter seems actually to have been recorded[2] for at least eight of Frenkiel and Katz's smoke puff observations; runs number 6, 7, 13, 16, 18, 20, 9 and 11. The observed puff diameter is clearly not the same quantity as the (root mean square) dispersion of diffusion theory. The dispersion increases with time indefinitely. It is for this reason that other workers, starting with Roberts[11] (and including Frenkiel and Katz) have interpreted the visible smoke puff outline as a line-of-sight integrated smoke concentration value. According to this interpretation, it was shown by Gifford[12] that Frenkiel and Katz's smoke puff data (among others) support the predictions of the theory of relative diffusion. The observed puff dispersion proceeds at first according to a power of time less than unity, as long as the influence of the initial puff size is still dominant. But after about 10 sec. (for these puffs), the dispersion, but not the puff diameter, is found to obey a $t^{3/2}$ law for the remainder of the puff's visible lifetime.

The high correlations of smoke puff diameter observations with the assumed dispersion law $(t + 3)^{0.87}$, obtained by Clarenburg and Tang, stem from two separate, unrelated effects, neither of which has been considered by them: (*a*) At first, smoke puff diameters do increase in proportion to a power of time less than unity; this initially slow spreading does not, contrary to Clarenburg and Tang's assumption, reflect the degree of turbulence present, or the shape of the one-point Lagrangian autocorrelation function. Instead, it reflects primarily the influence of the initial puff size, according to the prediction of the theory of relative diffusion. (*b*) Later, when the influence of the initial puff size decreases to zero, relative diffusion proceeds at an accelerating rate, that is, according to a power of time greater than unity. The puff diameters, on the other hand, reach a maximum and then actually decrease with time. This is, of course, a purely optical effect, and does not reflect any corresponding decrease in the real turbulent diffusion-rate. In fact, the higher the real turbulent diffusion, the more marked this latter effect should be.

For the above reasons, it is difficult to agree with the conclusion by these authors that their theoretical results are in good agreement with these experimental data.

PHYSICS

Velocity of Light emitted by a Moving Source

THE theory of special relativity is based on two main postulates, namely, the principle of relativity and the principle of the constancy of the velocity of light. If it is assumed that Maxwell's equations are correct and obey the principle of relativity, then the principle of the constancy of the velocity of light follows. The experimental evidence usually quoted in favour of the second principle is de Sitter's analysis of double stars. However, the principle has not been confirmed by experiments carried out in the laboratory using terrestrial sources. The need for such an experiment has been stressed recently by Dingle[1]. If the velocity of light is to have the same numerical value in all inertial frames then the velocity of light must be independent of the velocity of the source of light.

Generally, π^0-mesons decay into two γ-rays each having energy ~ 60 MeV. if the π^0-mesons decay when they are at rest relative to the laboratory. If the π^0-mesons are moving relative to the laboratory when they decay, then the source of the γ-rays is moving relative to the laboratory. It is known that this motion changes the energy and frequency of the γ-rays corresponding to the Doppler effect. If the principle of the constancy of the velocity of light were not correct then the velocity of the γ-rays from π^0-decay should vary depending on the velocity of the π^0-mesons relative to the laboratory when they decayed. Hence, if the velocity of the γ-rays arising from π^0-decay were measured, then it should afford a direct laboratory test of the principle of the constancy of the velocity of light. Let the π^0-mesons be produced in nuclear interactions inside the crystal of one scintillation counter by charged primaries (for example, protons $\sim 10^9$ eV. from an accelerator). The ionization produced in the crystal gives rise to fluorescence which is converted into an electrical signal by a photomultiplier. Any π^0-mesons produced will decay in a time $< 10^{-14}$ sec. so that the time of production of the γ-rays can be taken to be the time of entry of the primary particle. Let one of the γ-rays produce an electron pair in a second scintillation counter spatially separated from the first. The ionization produced by the electrons causes fluorescence in the crystal which is converted into an electrical impulse by the second photomultiplier. The time delay between the two electrical pulses can be measured electronically by several methods, for example, the first pulse could be used to trigger an oscilloscope and the position of the second pulse noted. With a separation of one metre the time delay would be $\sim 3 \cdot 3 \times 10^{-9}$ sec. if c were equal to 3×10^{10} cm./sec. If the velocity of the γ-rays depended on the velocity of the parent π^0-mesons then this time delay should vary depending on the velocities of the π^0-mesons. The main experimental difficulty would be to be sure that the coincidences observed would be due to the above events. As a check, the scintillation counters could be placed inside a large cloud chamber so that it could be checked that only one primary entered the first scintillation counter and that an electron pair was actually produced in the second counter. From the energy and direction of the electron pair, as observed in the cloud chamber, one could calculate an approximate value for the velocity of the parent π^0-meson.

It is probable that some other nuclear or meson process might prove more convenient to use in practice. A possibility might be to use a K-meson beam. Sometimes a K-meson emits π^0-mesons which afterwards decay into γ-rays. If the K-mesons were passed through a series of scintillation counters the positions and time of decay of the K-meson could be determined sufficiently accurately. The γ-ray detector could be placed off axis at a distance from the K-meson beam and the time delay measured.

The fact that in principle the experiment could be performed is of considerable interest even if it proved impossible to carry it out in practice. It has often been suggested that a direct experimental check of the principle of the constancy of the velocity of light is impossible since one would have to assume it to be true in order to synchronize the spatially separated clocks. In the above experiment one would not use two clocks but two crystals and photomultipliers, which would feed electrical signals into an apparatus which measures time intervals and which need not move before and during the experiment. When the events occurred, electrical signals would be sent along electrical cables to the timing machine and the delay in the transmission of the information could be allowed for once and for all by placing the two scintillation counters close together, and sending charged particles through both crystals and adjusting the lengths of the connecting cables until the pulses from both counters arrived simultaneously at the timer. The crystals and photomultipliers could then be moved apart without changing the length of any connecting leads. The delay in the receipt of information after the events would remain independent of the separation of the detectors if the velocity of electromagnetic disturbances in the connecting cables is independent of the directions and orientations of the connecting cables and is not changed when the cables are moved about. The usual method of synchronizing spatially separated clocks, as discussed in the text-books, is to use light signals which are assumed to travel in straight lines. In the present case the signals from the events can travel in curved paths such that the delay remains independent of the separation of the crystals and photomultipliers; the actual timing mechanism is not moved. In fact, in order to check the second principle one need not adjust the zero as described above, but one need only observe whether or not the time difference between the pulses from the two counters is the same whatever the velocity of the parent π^0-mesons relative to the laboratory when they decay.

Absolute Measurement of Average Energy lost by Very Soft X-rays per Ion Pair in Air

FIG. 1 gives a survey of measurements made so far of W, the average energy lost by photons and particles per ion pair in air. At energies exceeding 10 keV. W is practically constant. At less than 10 keV. a tendency to higher values of W is indicated. The fairly large discrepancies between some of the results, especially at low energies, caused us to carry out an absolute measurement of W with very soft X-rays[1].

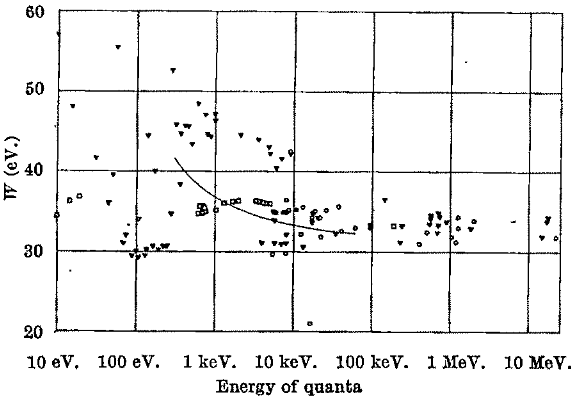

Fig. 1. W as a function of the energy. W for heavy particles is plotted in terms of the energy of electrons having the same velocity. ○, Photons ; ▽, electrons ; □, heavy particles

The measuring method is based on the equation, $W = nE_q/z$. The number n of monochromatic X-ray quanta of the energy E_q, produced by the filter difference method[2] has been measured by a total absorbing cæsium iodide scintillation counter. The crystal was enclosed in a container with a window of two aluminium foils, each 6·4μ thick, and mounted on the multiplier. The absolute counting was proved in preparatory experiments ; the readings are independent (*a*) of the place of absorption in the crystal and (*b*) of the voltage across the electrodes of the photomultiplier in a certain range. The number z of ion pairs in air produced by the quantity of energy nE_q has been measured by a total absorbing standard ionization chamber[3]. The required corrections have been calculated and determined experimentally.

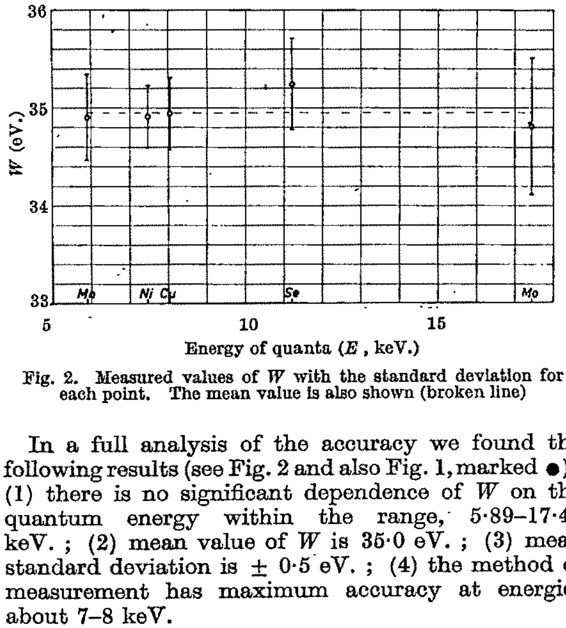

Fig. 2. Measured values of W with the standard deviation for each point. The mean value is also shown (broken line)

In a full analysis of the accuracy we found the following results (see Fig. 2 and also Fig. 1, marked ●) : (1) there is no significant dependence of W on the quantum energy within the range, 5·89–17·44 keV. ; (2) mean value of W is 35·0 eV. ; (3) mean standard deviation is ± 0·5 eV. ; (4) the method of measurement has maximum accuracy at energies about 7–8 keV.

Similarity in Behaviour between Gas Bubbles in Liquid and Fluidized Solid Systems

Davidson *et al.*[1] have noted a marked similarity between the behaviour of gas bubbles injected into beds of solids which were gently fluidized and gas bubbles rising in a liquid. Within the narrow range of main fluidizing air velocity used for beds of glass beads, silver sand and swede seeds, the velocity of rise of bubbles, U, was found to depend only on the volume of the bubble, V, and agreed with the semi-empirical formula :

$$U = 0{\cdot}792\ V^{1/6}g^{1/2} \qquad (1)$$

derived by Davies and Taylor[2] for spherical capped gas bubbles in an inviscid liquid.

In this Department, using a γ-radiation absorption technique, the variation in voidage has been assessed when a measured stream of gas was injected into a similarly gently fluidized bed of 0·8 mm. diameter ballotini. The injection nozzle was clear of the base of the bed. It was found by calibration that change in observed count-rate was, to a first approximation, proportional to the change in voidage in the radiation beam over the voidage variation encountered. Thus it was possible to estimate an effective void residence time along the path of the radiation beam. By scanning the face of the column it was possible to measure an average projection of the voidage contours within the column and from this to measure directly the breadth of the injected disturbance—the bubble diameter. It was assumed that the bubbles were spherical on formation at the nozzle and then rose with the velocity given by equation 1 ; no allowance was made for interaction between bubbles in a chain. The bubble frequency to give the measured void residence time was calculated and Fig. 1 shows the relationship between this frequency and the rate of gas injection for two nozzle diameters (0·16 in. and 0·096 in.).

The general form of Fig. 1 shows that the bubble frequency, within the general scatter of results, is approximately constant at 22 per sec. for the higher injected gas-flow rates and that below injection-rates of 50 c.c./sec. there is a marked tendency for this frequency to rise. This is closely in accord with the results published by Calderbank[3] in a review of the behaviour of bubbles formed when air is injected into water through similar sized orifices. Thus these

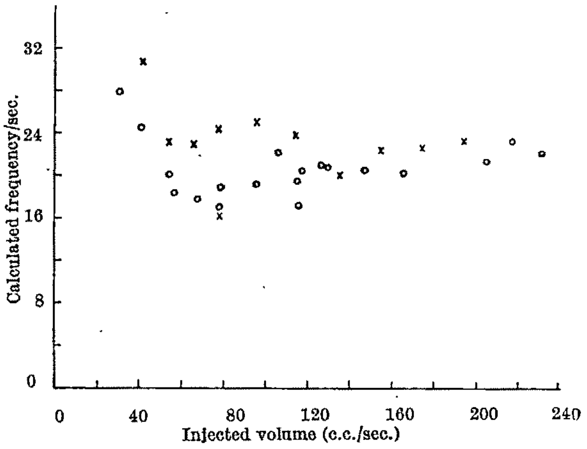

Fig. 1. Relationship between injected gas volume and calculated bubble frequency. ○, 0·16 in. diam. nozzle ; ×, 0·096 in. diam. nozzle

observations also show a similarity in behaviour between gas bubbles in liquid and fluidized solids systems even though the actual mechanism of bubble formation in these two systems must obviously be quite different.

Nucleation in Agitated Solutions

Mechanical disturbances are known to speed the onset of nucleation in supersaturated solutions. Early workers[1] demonstrated that severe mechanical shock could induce nucleation in metastable solutions at temperatures well above the so-called 'metastable limit', and more recent work[2] has shown that mechanical stirring can cause rapid nucleation in unseeded solutions which will not normally form nuclei under quiescent conditions. Published work to date has not given any indication of the effect of varying the intensity of agitation on the tendency of an unseeded solution to form nuclei under any given set of conditions, but it is generally assumed that more vigorous agitation increases this tendency.

Investigations carried out in these laboratories on nucleation and growth conditions in a pilot-scale Oslo crystallizer operating with unseeded solutions of ammonium dihydrogen phosphate have confirmed that the critical supersaturation, defined here as the degree of supersaturation at which nuclei are first observed in a solution being cooled at a constant rate, is dependent on the rate of circulation of the liquor, that is, on the degree of turbulence. Less supersaturation is required for nucleation to occur at the higher rates of flow.

It was observed, however, that at low rates of circulation, represented by Reynolds numbers of about 700–1,400 in a column of 3 in. diameter, the degree of supersaturation necessary for nucleation was not apparently reduced by increasing the turbulence. Unfortunately, variations in the value of the critical supersaturation were here of the same order as the experimental error. Accordingly, recourse was made to a smaller apparatus where conditions were more easily controlled. A glass *T*-stirrer was used in a small baffled beaker. The solutions of ammonium dihydrogen phosphate were covered with a thick layer of liquid paraffin and cured for about 30 min. at 10 deg. C. above their saturation temperatures before each run. Accidental inoculation by dust particles was thereby largely eliminated and reproducible results were obtained.

Whereas gentle stirring causes nucleation in solutions which are otherwise stable, and sufficiently vigorous stirring creates an even greater tendency to form nuclei, the transition may not be continuous ; no simple relationship between the critical supersaturation and the intensity of agitation has been found. In general, a plot of critical supersaturation against rate of agitation is not a single smooth curve ; in fact, a portion of the curve may have a reversed slope (see Fig. 1) indicating a region where an increase in the agitation reduces the tendency to nucleate. So far as is known, this is the first experimental evidence of such a phenomenon.

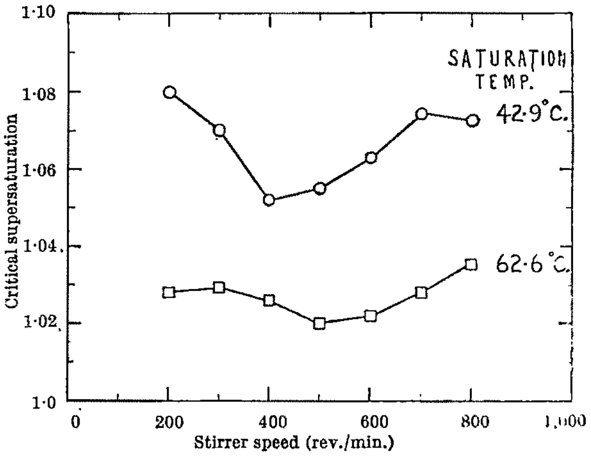

Fig. 1. Critical supersaturation (solution concentration/saturation concentration) versus stirrer speed for aqueous solutions of ammonium dihydrogen phosphate

Nucleation in liquids has hitherto been considered as consisting of two stages : a diffusional transport step which is aided by agitation, and a surface reaction step when growth of the sub-nucleus occurs, the latter not being influenced by agitation. It would now appear that a third effect may also operate, which impedes the growth of, or disrupts, the sub-nuclei, and that this effect may predominate in certain circumstances.

The work, which so far has been confined to aqueous solutions of ammonium dihydrogen phosphate with saturation temperatures in the range 40–70° C., is being extended to cover a wider range of concentration and other solutes, to determine whether this effect is of general occurrence or specific to a limited range of conditions, and to attempt a theoretical explanation.

Origin of the Word 'Neutron'

The word 'neutron' has been attributed to Rutherford by Glasson[1] and to W. D. Harkins[2] by Glasstone[3]. It appears likely that it was not used by either Rutherford or Hawkins before about 1920. In both cases, the neutron was a hypothetical combination of a hydrogen nucleus (also called a 'positive electron' or 'proton') and an ordinary negative electron.

I wish to point out that William Sutherland used the word in almost exactly the same sense in two papers published in 1902, in the first of which there is the passage[4]:

"As it would be convenient to have symbols different from the operational + and − to distinguish the two sorts of electrons, I propose to use the musical types ♯ for the + electron and ♭ for the − electron, and ♮ for the neutron, which consists of the ♯ and ♭ united to form that electric doublet which gives to the æther its electric and magnetic properties."

Phenomena occurring at Electrically Stressed Metallic Surfaces in Vacuum

CERTAIN hypotheses put forward to explain the mechanism of electrical breakdown of high vacuum, between metallic electrodes, rely on the removal from the electrode surfaces of aggregates of material[1,2]. Such aggregates have become known as 'clumps'. By means of radioactive layers on the electrodes or spectroscopic analysis, material transfer during the pre-breakdown phase has been shown to occur[3-6]. Breakdown has been initiated by the introduction of particles of electrode material in the gap[7]. The occurrence of points and pits on the electrodes has been confirmed by examining the electrodes microscopically before and after voltage stressing, while actual growth and tearing off of small points several μ in length has been photographed during an increase in voltage[8,9]. The latter observations showed that the points appeared to grow only on the anode, a fact supported by an observation that indicated the breakdown voltage was proportional to the tensile strength of the anode[10].

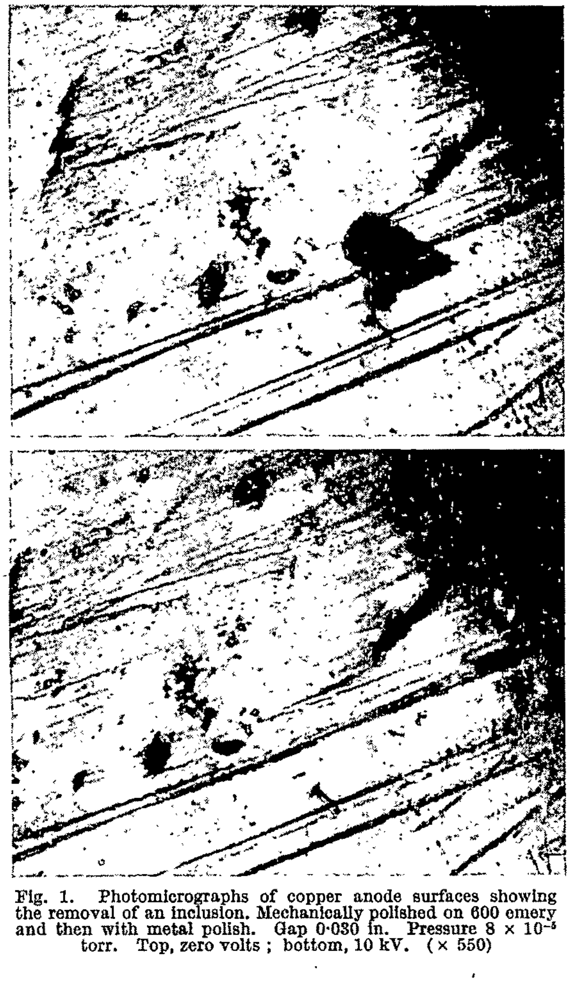

Fig. 1. Photomicrographs of copper anode surfaces showing the removal of an inclusion. Mechanically polished on 600 emery and then with metal polish. Gap 0·030 in. Pressure 8×10^{-5} torr. Top, zero volts; bottom, 10 kV. (× 550)

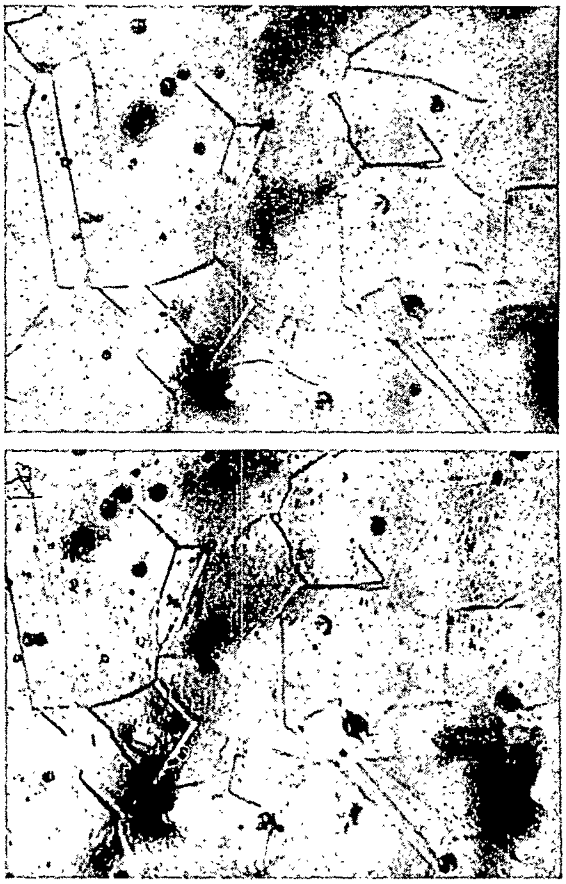

Fig. 2. Photomicrographs of electrolytically polished copper anode surfaces showing the appearance of 'spots'. Gap 0·015 in. Pressure, 8×10^{-5} torr. Top, zero volts; bottom, 24 kV. (× 550)

The actual observation of the growth of points was the first direct visual evidence that such multi-atom clumps were pulled out of the surface and transported across the gap. An apparatus was designed, before the foregoing results were known to us, in which the surface could be observed normally and with the voltage applied. It consisted essentially of an anode and cathode mounted in a continuously pumped vacuum cell. The cathode was in the form of a copper disk in the centre of which was a hole with bevelled sides, the diameter of the hole opposite the anode being 0·34 in. Located behind the cathode and in line with the hole was an 8-mm. objective lens, of 0·5 N.A., which fitted into a Vickers microscope. The anode was in the form of a 45° copper cone, the top of which was ground flat so that it just fitted the field of vision through the microscope. Analysis showed the copper to be about 99·5 per cent copper and 0·3 per cent oxygen with normal commercial impurities. Direct voltages were used and the breakdown current was limited by a 2-megohm series resistor. The pressure lay between 5×10^{-5} and 9×10^{-5} torr. Before some tests the anode was polished with emery cloth down to 600 grade and then with 'Silvo' and finally washed in water, alcohol, and ether; in other cases it was electrolytically polished.

Some results of a preliminary series of tests are now reported as they confirm other investigators' results and give further information. With the gap set at 0·03 a large inclusion 2×10^{-3} cm. in diameter was seen to disappear from the anode at about 10 kV. or a 'stress' of $1·3 \times 10^5$ V./cm. Its removal did not cause breakdown. The effect is shown in Fig. 1, and although scratch marks can be seen from where the inclusion vanished they appear to be less intense than on either side of the inclusion. Thus it may well have been a piece of embedded cleaning material. Razin[9] also reports a clump tens of microns in size, being pulled off at a stress of 2×10^5 V./cm.

In certain cases as the voltage was increased a different type of phenomenon took place in that 'spots' were seen to appear on the anode surface, as shown in Fig. 2. In the case shown the anode had been electrolytically polished, the gap was 0·015 in. and the spots arose at 24 kV. This corresponds to a stress of $6·3 \times 10^6$ V./cm. With the mechanically polished surfaces described earlier the spots arose at a stress of about 4×10^5 V./cm. The size of the spots is about $1·5 \times 10^{-4}$ cm. diameter, which compares well with clump sizes estimated from the Slivkov hypothesis[2] of 5×10^{-5} cm. and with the smaller marks observed by Schwabe[8] of 2×10^{-4} to 5×10^{-4} cm. Cranberg[1] postulated the clump size to lie between 10^{-2} and 10^{-6} cm. The number of spots per square centimetre of electrode surface is of the order of 10^6. In several runs it took a further increase of voltage to cause breakdown but in others breakdown was immediate.

GEOLOGY and MINERALOGY

Age of the Orogeny and Granites in South-West England

The Dartmoor and related granites form one of the key points in the revised geological time-scales of Profs. A. Holmes[1] and J. L. Kulp[2]. Therefore, their stratigraphic relationships need to be determined as precisely as the field evidence will allow. Kulp *et al.*[3] write that "while the Dartmoor granite is almost certainly post-Lower Westphalian, Lower Stephanian strata in Somerset are affected by the same fold system and it is therefore probable that the granites are of latest Stephanian or Permian age". It is by no means generally accepted, however, that the fold system in Devon and Cornwall is of the same age as that in the Somerset coalfield[4,5]. Indeed, Holmes[1] adopts a suggestion from Owen that the granites may have been emplaced in Upper Westphalian times and that the Pennant Sandstone of South Wales "may be the product of the rapid erosion of the rising Cornubian chains"[6]. A brief discussion of the available evidence therefore seems desirable.

The granites invade a folded and faulted stratigraphical succession in which, *at the present level of erosion*, the youngest sediments so far recognized by fossils are referable to the Upper Gastrioceras Zone of the Lower Westphalian[7–9]. It is likely, however, that a considerable tectonic thickness of deformed Palæozoic strata (perhaps many thousands of feet in the Dartmoor region) was originally present above the structures now seen[10] bordering the exposed granites. It therefore seems reasonable to suppose that even younger Westphalian, and perhaps even Stephanian sediments could well have been present in the deformed mass into which the granites were emplaced. Prentice's sedimentological conclusions from the Bideford area[11] support this view.

It appears that only unaltered Palæozoic rocks from the upper part of this deformed mass were being eroded in basal New Red Sandstone times[12]. Later New Red sediments contain contact-metamorphosed Palæozoic rocks, while the Lower Cretaceous Wealden sediments of southern England are thought to provide "the earliest evidence of the uncovering and denudation of the [Dartmoor] granite itself"[13].

It therefore seems preferable on the present evidence to regard the main orogenic movements in Devon and Cornwall as being of essentially the same age as those in the nearby Somerset coalfield, which are known to affect Lower Stephanian strata[14,15]. I support the assignment of the granites to the Permian[2] rather than to the latter part of the Carboniferous period[1]. The position of these granites in the geological time-scale will presumably affect the length of time to be allotted to the Carboniferous period, a matter of some importance in Carboniferous stratigraphy.

Thanks are due to Prof. A. Holmes for discussion in correspondence and to Prof. P. Allen, Prof. J. Sutton and Dr. R.St.J. Lambert for their comments.

Attempted Low-Temperature Syntheses of Kaolin Minerals

Although kaolin minerals appear to be formed in Nature under acidic conditions at relatively low temperatures and low water-vapour pressures, their synthesis in the laboratory under similar conditions has been found exceptionally difficult. It appears that a proper choice of many variables is essential. In previous investigations[1,2], individual kaolinite crystals have been obtained by ageing mixed alumina and silica gels for 2 months at 100° C. and under *p*H conditions around 4·5, but the crystalline yield was extremely poor and the kaolinite could be proved only by single-crystal, electron diffraction methods; X-ray diffraction failed to detect the small yield. It seems that the ready polymerization of silica, with aluminium incorporated in the structure, inhibited the crystallization of a layer structure. Similar difficulties are not encountered in forming hydrous magnesian silicates.

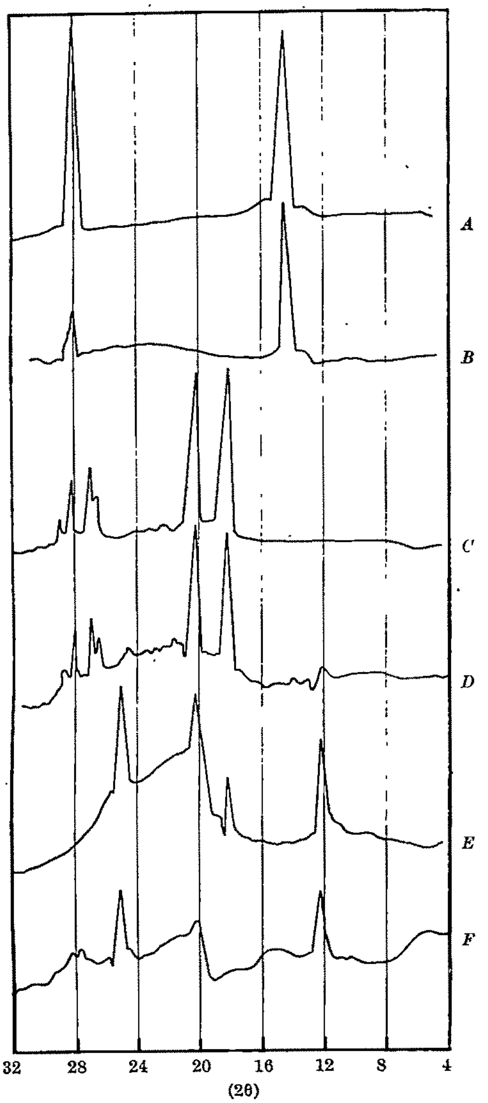

Fig. 1. X-ray diffractometer patterns; copper $K\alpha$ radiation. *A*, boehmite; *B*, boehmite obtained from gibbsite in sealed tube at 150° C.; *C*, gibbsite; *D* and *E*, gibbsite partially transformed to kaolin mineral; *F*, gibbsite wholly transformed to kaolin mineral

In the present experiments, gibbsite, $Al(OH)_3$, has been used as a source of alumina, together with silica either as a gel, 'Ludox', or in solution as ethyl silicate. The experiments have been conducted in sealed glass tubes at 150° C. and about 5 atm. water-vapour pressure, and with vigorous end-over-end agitation. The *p*H was controlled mainly by $N/10$ hydrochloric acid, but in experiments lasting 1–3 weeks the *p*H value often varied and a better control is desirable.

The results are illustrated in Fig. 1 by diffractometer diagrams. When the final *p*H exceeds 1·9, gibbsite is the only crystalline phase observed (cf. diagram *C*). When the *p*H remains below 1·5, a kaolin mineral replaces the gibbsite (cf. diagrams *D*, *E*, *F*). Electron micrographs show plate-like forms and also rod-like forms having some resemblance to halloysite. Reversible swelling and shrinkage behaviour is readily followed by X-ray diffraction, and each cycle of operations seems to improve the crystal structure. Whereas gibbsite in the absence of silica becomes transformed to boehmite at 150° C. under the conditions of the experiments (cf. diagrams *A* and *B*; also ref. 3), in the presence of silica the formation of boehmite is completely inhibited. Probably the instability of the gibbsite structure facilitates its reaction with silica to develop an alumino-silicate layer structure.

Further experiments are in progress in which temperature and *p*H will be controlled with more precision. This investigation forms part of Project 55, sponsored by the American Petroleum Institute.

CRYSTALLOGRAPHY

Spiral Formation on Natural Crystalline Sulphur

Recently, observations of the growth spirals suggested by Frank's theory[1] have been reported on many different substances.

This communication records some interesting observations of growth spirals originating from screw dislocations on the (001) faces of natural sulphur crystals. The observations were made by means of an ordinary metallurgical microscope, using bright-field illumination. The heights of the steps were measured using interferometric techniques[2] and the values found range from 5000 Å. to 100 Å., showing that growth-promoting dislocations are of multiple strength.

Most of the faces investigated showed one spiral only, covering the whole area, which seems to prove that sulphur crystals must be extremely perfect.

Fig. 1 shows a spiral originating from a right-handed dislocation. Besides this elementary type of spiral, several other more complicated growth patterns, for

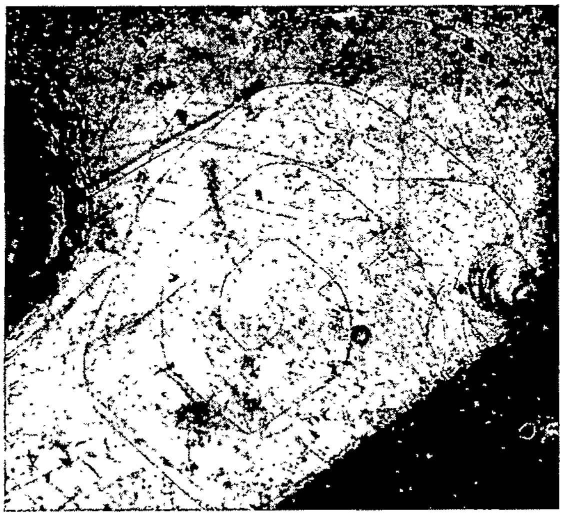

Fig. 1 (× 90)

two, three or larger numbers of dislocations ending on crystal faces, have been photographed.

The observed density of dislocations varies widely on different specimens, ranging from a few to a maximum of approximately 10^4 per sq. cm. On any one crystal they are predominantly of the same hand.

A more detailed account of these observations will be submitted elsewhere.

Growth Spirals on Synthetic Magnetoplumbite Crystals

In connexion with a study of crystal growth from lead oxide and lead oxide–lead fluoride melts, we have recently observed growth spirals on (0001) faces of tabular magnetoplumbite ($PbFe_{12}O_{19}$) crystals. The spirals on crystals obtained from lead oxide–lead fluoride melts are polygonal, relatively open, and show concave growth fronts as well as reversed curvatures near the outer edges of the crystals. The step heights appear to be small multiples of the unit cell dimension in the *c* direction. The spirals on crystals grown from lead oxide melts are polygonized to various degrees, are more tightly wound, and exhibit greater step heights.

The magnetoplumbite crystals showing well-defined spirals were located on the top surfaces of melts from which yttrium–iron garnet crystals were grown by procedures approximating those suggested by Nielsen[1,2]. The spirals were observed with a petrographic microscope, using bright-field illumination. Fig. 1 shows a typical growth spiral on the surface of a crystal still attached to the top surface of a solidified lead oxide–lead fluoride melt. The small particles covering the crystal surface and decorating the step are believed to be flux components that solidified when the crucible was removed from the furnace (at about 1,000° C.). These particles were removed without otherwise altering the surface, by treating the surface with dilute nitric acid. Step heights were measured by a thin-film interferometric technique of the type described by Tolanski and Omar[3]. The value obtained for the height of the step near the origin of this spiral was 48 Å. The unit cell dimensions of a typical crystal (exhibiting a growth spiral) were determined to be $a = 5{\cdot}91$ Å., and $c = 23{\cdot}1$ Å., and the spiral was shown to be on the (0001) surface by X-ray methods. The step height (and Burgers vector of the screw dislocation(s) responsible for the spiral) on the surface of this crystal is approximately twice the unit cell dimension in the *c* direction. Dissociation of the spiral into two steps can be seen in the reversed curvature region (see below). The step height on a second spiral of similar appearance was determined to be about 68 Å., or approximately three times the unit cell dimension in the *c* direction. The displacement of interference fringes across the spiral step on many of the crystals was observable, but too small to measure. It is likely that these steps were a unit cell in height.

An interesting feature of the spiral shown in Fig. 1 is the partial reversal in curvature. A uniform supersaturation across the crystal face should lead to an equilibrium growth spiral that is approximately Archimedian in shape[4]. In the presence of concentration gradients, however, the shape of the spiral will be altered. An increase in supersaturation between the centre and the edge of a crystal face frequently occurs during crystal growth, and the suggestion has been made by Amelinckx[5] that a suitable gradient of this type may result in a complete reversal of spiral curvature. The spirals on magnetoplumbite crystals grown from lead oxide–lead fluoride melts have a shape that suggests a radial increase in supersaturation just sufficient to produce a reversal in curvature from about one-half of the radius to the edge of the face. The effect can be clearly seen in Fig. 2. Both right- and left-handed spirals are present on the surface of this crystal and both types show curvature reversals near the edge of the face. One can also see that the nearly straight segments of the spirals in Figs. 1 and 2 are slightly concave. The concave growth fronts may also be the result of an increase in growth-rate (supersaturation) with increasing distance from the centre of the crystal.

Numerous multiple-step spirals and complex systems of spirals were characteristic of the surface

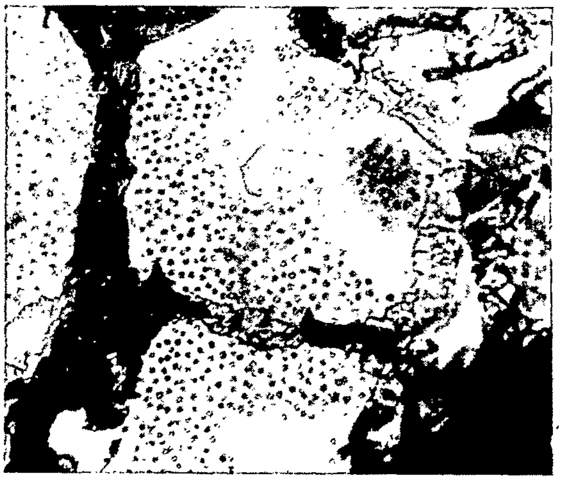

Fig. 1. Growth spiral on a magnetoplumbite crystal grown from a lead oxide–lead fluoride melt. (× c. 273)

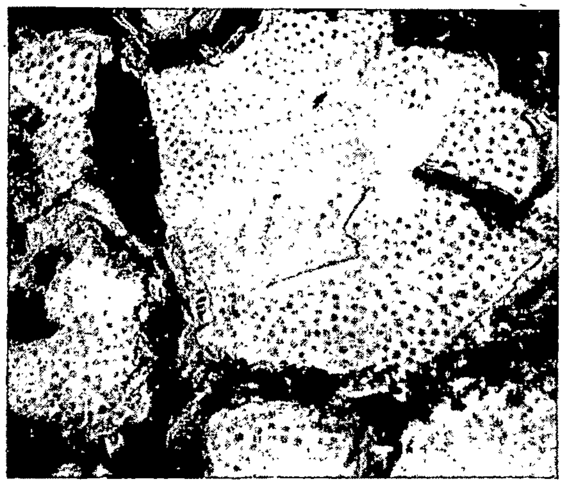

Fig. 2. Right- and left-handed growth spirals on a magnetoplumbite crystal. (× c. 273)

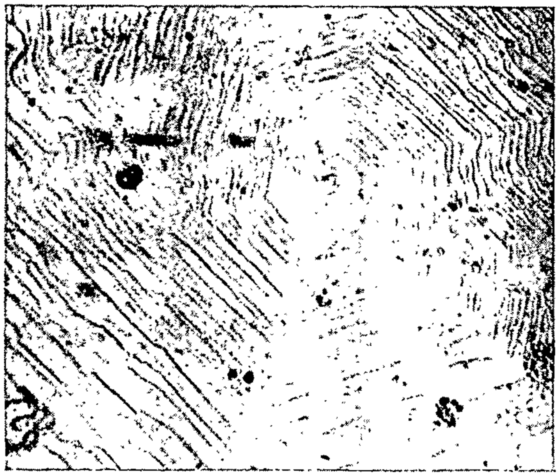

Fig. 3. Multiple-step growth spiral on a magnetoplumbite crystal grown from a lead oxide melt. (× c. 273)

features observed on magnetoplumbite crystals grown from lead oxide melts. Fig. 3 shows a tightly wound, multiple-step spiral on the surface of a crystal grown from a lead oxide melt. A value of 163 Å. (7 unit cells in the c direction) was obtained for the maximum height of a single step on this spiral. At higher magnifications, dissociation of the steps into smaller components was observed in several regions. The fact that these steps are more closely spaced than those observed on the faces of crystals grown from the lead oxide–lead fluoride melts is probably the result of higher supersaturations during growth. Such a result is consistent with the fact that magnetoplumbite is the major phase in the lead oxide system and a minor phase in the lead oxide–lead fluoride system.

CHEMISTRY

Catalytic Activity of Coloured Alkali Halides

The properties of alkali halides containing colour centres are in some respects similar to those of semi-conductors: it was therefore thought to be worth while to determine whether such alkali halides have any of the catalytic properties of semi-conductors. The oxidation of carbon monoxide was chosen as a test reaction, as this reaction is readily catalysed by semi-conductors at low temperatures[1].

The halides investigated were sodium and potassium chlorides, potassium iodide and potassium bromide; all were of reagent grade purity and were used without further purification. The salts were thoroughly dried and ground, the portion between 150 and 300 mesh being used in the experiments.

Carbon monoxide was prepared by dehydrating formic acid with sulphuric acid, the gas being purified by passage through potassium hydroxide and magnesium perchlorate towers and finally through a liquid-air trap. Cylinder oxygen was passed through the same purification train, and probably contained traces of nitrogen and argon. A stoichiometric mixture of carbon monoxide and oxygen was used in all experiments.

The reaction vessel was a 'Pyrex' cylinder which could be fitted with a vapour-jacket for temperature control. The reactor, which had a volume of approximately 45 ml., was fitted with a thermocouple well, the end of which was always in the salt under investigation. Pressures were measured with both mercury and di-*n*-butyl phthalate manometers.

In a typical experiment, approximately 1 gm. of the ground salt was spread in an even layer over the bottom of the reactor. The reactor was then sealed into the vacuum system and heated to 250° C. for 10 min. at a pressure of less than 10^{-5} mm. mercury. The reactor was then brought to room temperature under vacuum, and dry air admitted to a pressure of 0·1 mm. mercury. The discharge from a Tesla coil was then played over the reactor for several minutes to produce colour centres in the salt. The reactor was then rapidly pumped out to a high vacuum ($<10^{-5}$), brought to the required temperature, and a sample of the carbon monoxide–oxygen mixture admitted. The manometer readings were followed as a function of time and, if the room temperature varied during the run, corrected for changes in the density of the manometric fluid. The manometer readings were also corrected for pressure changes in the non-thermostatted dead space of the reactor if there was any change in room temperature.

Experiments were carried out from 35° C. to 125° C. (above which temperature the colour centres bleached rapidly), with initial gas pressures of 10–250 mm. mercury. Runs were made both in the dark and in the presence of normal laboratory lighting. In no case was any evidence of catalytic activity obtained; although 0·2 per cent reaction in a 3-hr. period could have been detected. At the higher pressures a rapid, poorly reproducible decrease in pressure was observed immediately on admission of the gas. This decrease amounted to approximately 0·5 per cent of the initial pressure. This decrease could not be observed at the lower pressures, presumably because of drainage errors in the oil manometer.

Although the adsorptive properties of alkali halides have not been investigated in detail, it would seem from the work of Tompkins[2] that this pressure decrease might be due to a small adsorption of carbon monoxide. The work of Orr[3] suggests that oxygen adsorption would be negligible in the temperature-range of this work.

Experiments with the same gas mixture, in the same system, using nickel oxide as a catalyst, gave results comparable to those previously reported[1].

Determination of Very Small Amounts of Hydrogen Peroxide

It has been found that radiation doses of a magnitude as low as 10 r. damage cells in culture and interfere with their multiplication[1,2]. Although the damage is to be ascribed primarily to short-lived radicals produced by the rays rather than to the hydrogen peroxide also made, it is desirable to study the biological effects of small concentrations of this substance.

In this connexion, a very sensitive method for the determination of hydrogen peroxide is needed. The efficiency of ionizing rays in producing chemical species is measured by the *G* value, which is defined as the number of molecules formed per 100 eV. of energy absorbed. Using γ-rays (cobalt-60), *G* values for hydrogen peroxide production of 1·05–1·31 were found at dose-rates of about 3×10^3 r./min.[3-8]. Therefore, a dose of 10 r. will give in 1 ml. water hydrogen peroxide of about 10^{-11} mole ($\sim 3{\cdot}5 \times 10^{-10}$ gm.).

To develop a suitable method, we started from the report by Andreae[9] that scopoletin (6-methoxy-7-hydroxy-1,2-benzopyrone) is oxidized stoichiometrically (1 : 1) by hydrogen peroxide with loss of its fluorescence, provided horse radish peroxidase is present. The fluorescence before and after interaction with peroxide was measured with a Beckman spectrophotometer model *DU*, adjusted for fluorimetry. 10^{-10} mole of hydrogen peroxide could be measured. In the present work the determination was made with a Galvanek-Morrison fluorimeter, mark *V* (Jarrell Ash Co.), as usually employed for the determination of uranium in solid sodium fluoride pills. In this way, the sensitivity of the method has been improved by about one magnitude for the concentration, and by two magnitudes for the quantity of hydrogen peroxide.

The method was tested with hydrogen peroxide solutions. The solvent water had to be very pure to avoid spontaneous decomposition of the solute. Twice-distilled conductivity water was distilled three more times. First, with alkaline potassium permanganate; secondly, with silver nitrate; and finally, without any addition in a quartz apparatus. Hydrogen peroxide ('Perhydrol *p.A.*', Merck) was added to this water to give a solution about 0·2 per cent, and the exact concentration determined by iodometry. This stock solution was stable when stored in silica in darkness. For use it was diluted in steps, and the concentration measured by the scopoletin method after each step.

For the purpose, 0·1 ml. of scopoletin solution, 0·1 ml. of horse-radish peroxidase (C. F. Boehringer) solution (concentration not critical), and 0·1 ml. of hydrogen peroxide solution were mixed. The amounts of scopoletin were chosen so that at most three-quarters were used up by reaction with the hydrogen peroxide. 15 min. after mixing, 0·3 ml. of 0·15 *M* borate buffer (*p*H 10·0) was added, exactly one-half of the mixture transferred to a platinum dish, and the fluorescence measured. To obtain the fluorescence of the intact scopoletin, a blank mixture was made by including 0·1 ml. water instead of the same amount of hydrogen peroxide solution.

In Fig. 1, the logarithm of the number of moles of scopoletin oxidized (S_{ox}) is plotted against the logarithm of the number of moles of hydrogen peroxide as calculated on the basis of the iodometry with the stock solution. Clearly the method is applicable over a large range of concentrations. In Fig. 2, the destruction of the fluorescence in aliquots of one and the same scopoletin solution (containing initially $3{\cdot}12 \times 10^{-11}$ mole) by varying quantities of peroxide is shown, and Fig. 3 contains a similar plot for an initial concentration of $2{\cdot}5 \times 10^{-12}$ mole. It will be noted that the inclinations of the straight lines in the graphs are exactly 45°, as required by the stoichiometry 1 : 1.

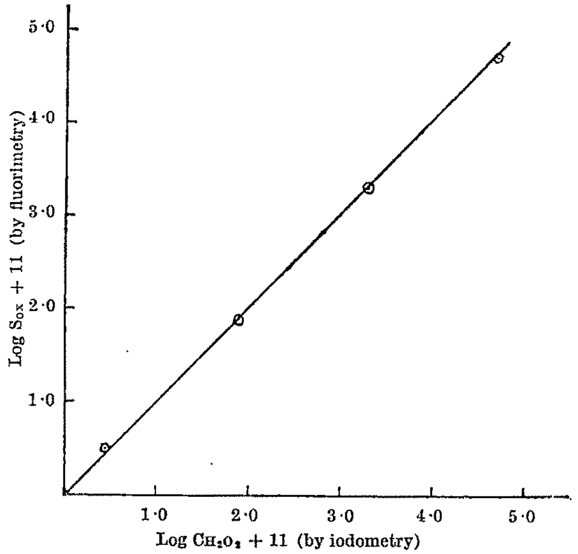

Fig. 1

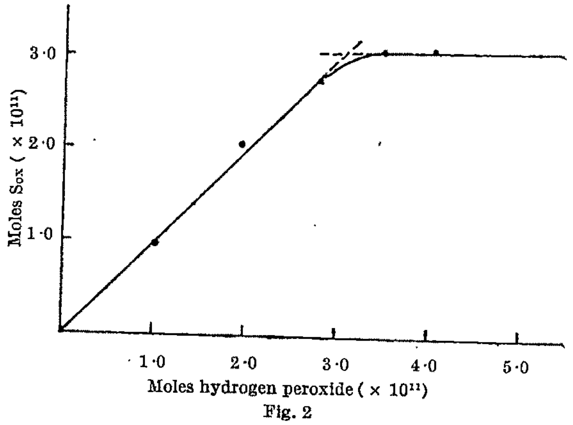

Fig. 2

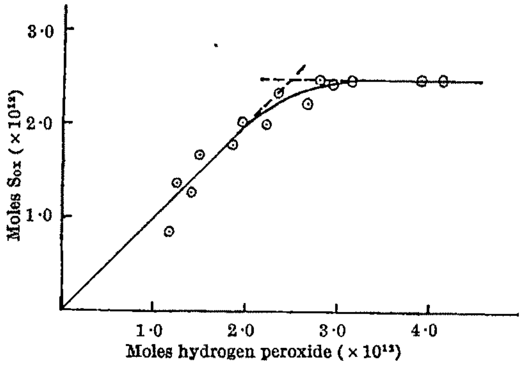

Fig. 3

It appears that in the range covered by Fig. 3 the limit of the method is reached. The scatter of the points in the lowest range is due to the fluctuations of the instrument when it works at its highest sensitivity. By proceeding statistically, that is, by measuring several identical samples in parallel and taking averages, the limit could be pushed down a little further.

In the method as used, the standard error is about 10 per cent in the measurement of $1\cdot5 \times 10^{-12}$ mole hydrogen peroxide, corresponding to a concentration of $1\cdot5 \times 10^{-11}$ mole/ml. in the initial solution, and to a radiation dose to this solution of about 15 r. Presumably even smaller concentrations and doses could be determined if the fluorimeter were adapted to take larger samples, or if the hydrogen peroxide could be diluted to a lesser extent by the reagents before measurement.

We thank the Jane Coffin Childs Memorial Fund for Medical Research for a grant and the Österreichische Studiengesellschaft für Atomenergie for the loan of the fluorimeter.

Note added in proof. By using more concentrated reagents, solutions of 5×10^{-12} mole/ml. have now been measured, corresponding to a dose of about 5 r.

Electron Spin Resonance Line-Widths in Solutions of Copper and Silver Dithiocarbamates

In previous publications the electron spin resonance data of dithiocarbamates of the coinage metals ($[RR'\mathrm{NCS}_2]_2Me$; Me = copper, silver or gold) have been used for a determination of valence states of the metals[1] and in a discussion of the bonding of the metal ions[2]. The copper and silver compounds exhibit very low effective spin-orbit coupling energy with small resonance anisotropy and unusually narrow lines. The small line-width makes it possible to analyse the influence on the width from a number of factors, and we shall briefly report on the effect of temperature, of dissolved oxygen and of different solvents.

In a liquid, where the paramagnetic molecules tumble at a sufficient rate, the position of the lines will mainly be determined by the isotropic parts of the spin Hamiltonian. However, in the cases where the hyperfine structure is anisotropic, the line-width will be dependent on the nuclear magnetic quantum number m_I. A theory for this effect was first given by McConnell[3], who used the results obtained by Bloembergen, Purcell and Pound for the nuclear relaxation. Recently, Kivelson[4] has re-examined the problem starting from the treatment given by Kubo and Tomita. The contributions to the longitudinal relaxation (characteristic time T'_1) and to the transverse relaxation (characteristic time T'_2) are given by Kivelson as :

$$\frac{1}{T'_1} = \frac{4\pi^2}{h^2}\left[\frac{1}{15}(\Delta g\beta B_0)^2 - \frac{1}{5}\Delta g\beta B_0 b m_I - \frac{1}{40}(b m_I)^2 + \frac{7}{40}b^2 I(I+1)\right]\frac{\tau_c}{1 + 4\pi^2\nu^2_0\tau^2_c}$$

$$\frac{1}{T'_2} = \frac{4\pi^2}{h^2}\left[\frac{4}{45}(\Delta g\beta B_0)^2 - \frac{4}{15}\Delta g\beta B_0 b m_I + \frac{1}{8}b m_I)^2 + \frac{3}{40}b^2 I(I+1)\right]\tau_c$$

The paramagnetic molecules are assumed to have axial symmetry. $\Delta g = g_{\parallel} - g_{\perp}$ is the g-value anisotropy and $b = 2(A - B)/3$ is related to the hyperfine structure anisotropy. B_0 and ν_0 are the static magnetic field and the microwave frequency at resonance. Rogers and Pake[5] showed that these formulæ correctly describe the frequency and the m_I dependence of the line-widths of the VO^{++} ion.

We have studied the dependence on temperature of the line-widths of acetone solutions of copper diethyldithiocarbamates ($\Delta g = 0\cdot065$, $b = -0\cdot79 \times 10^{-2}$ cm.$^{-1}$)[2]. The conditions for validity of the formulæ are well fulfilled; for example, $\Delta g/g = 0\cdot03 \ll 1$. The correlation time was estimated using the relation $\tau_c = 4\pi\eta r^3/3kT$ with $r = 3\cdot5$ Å. and where η is the viscosity[6]. ν_0 is about 9,130 Mc./s. Fig. 1*a* shows the variation with temperature of the width (measured between the points of maximum and minimum slope) of the $m_I = +\frac{1}{2}$ line for carefully deoxygenated solutions. In the low-temperature region the agreement with the calculated width ($= (1/2T'_1 + 1/T'_2)/\pi\sqrt{3}$) is good, but the fact that there is a minimum in the line-width at a certain temperature cannot be explained on the basis of anisotropy mechanisms alone. The exchange mechanisms suggested by Pake and Tuttle[7] and further developed by Kivelson[4] might provide an explanation for the increase in line-width with increasing temperature; but as their contribution to the width should be proportional to the concentration they probably do not account for the whole difference between the experimental and calculated widths. Spin-orbit interaction or mechanisms such as discussed by Al'tshuler and Valiev[8] might be responsible for the main part of the high-temperature width. All such phenomena should, however, be independent of m_I and from Fig. 1*b* it is clear that Kivelson's formulæ well predict the difference between the widths of two hyperfine lines. The contributions to the line-width from the quadrupole interaction as calculated by

Kivelson are also in general dependent on m_I, but for only one nucleus with $I = 3/2$, these contributions accidentally are independent of m_I.

Dissolved oxygen has a marked influence on the line-widths of both copper and silver dithiocarbamates. The width increases linearily with increasing partial pressure of oxygen while preserving the area under the absorption curve. From the solubility of oxygen in benzene[9] and the formulæ given by Bloembergen, Purcell and Pound[10] for dipolar broadening, the contribution from oxygen with $p_{O_2} = 760$ mm. mercury is estimated to be of the order of 0·1 gauss. Experimentally the result is about 5 gauss (the resonance of diphenylpicrylhydrazyl in benzene is also broadened by dissolved oxygen to about the same extent). The discrepancy again could be due to exchange effects and measurements at different temperatures should be carried out. However, the variation with temperature of the solubility of oxygen makes such experiments difficult.

There is also a solvent effect in the electron spin resonance spectra both on the widths and on the resonance parameters. The most pronounced effect we found in pyridine, where for $([C_2H_5)_2NCS_2]_2Cu$, the g-value is 2·0567 (in benzene 2·0453) and the hyperfine structure constant is $-0{\cdot}67 \times 10^{-2}$ cm.$^{-1}$ (in benzene $-0{\cdot}74 \times 10^{-2}$ cm.$^{-1}$). Similar solvent effects have been reported by Pake and Sands[11] and by McGarvey[12]. In mixtures of pyridine and benzene the lines have intermediate positions without appreciable broadening (Fig. 2), which shows that the exchange between solvent molecules close to the paramagnetic molecule must occur with a frequency higher than about $0{\cdot}5 \times 10^9$ c./s. This clearly demonstrates the inability of the dithiocarbamates to form complexes with pyridine as has also been demonstrated by chemical methods[13].

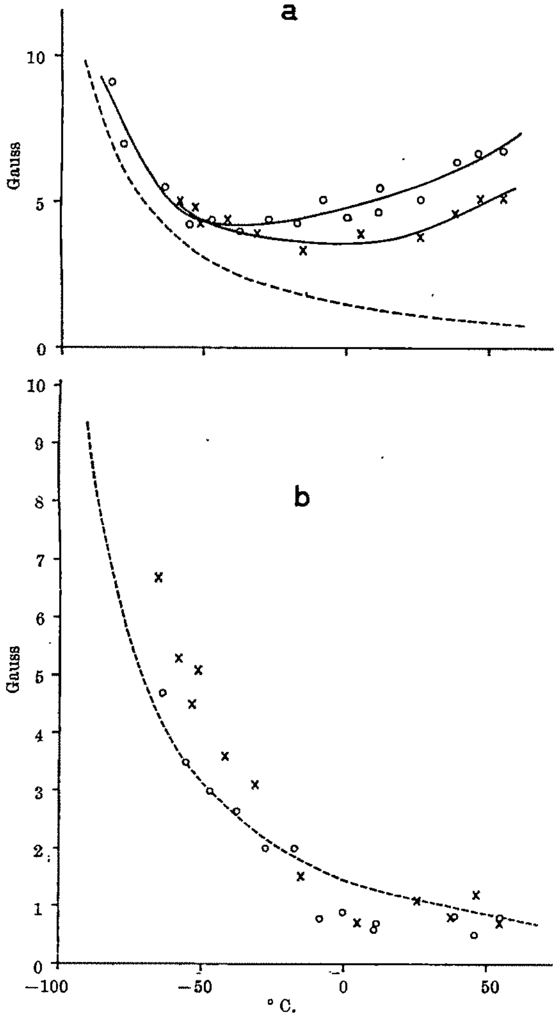

Fig. 1. Widths of hyperfine lines (measured between points of maximum and minimum slope) of 10^{-3} M and 10^{-4} M respectively acetone solutions of $[(C_2H_5)_2NCS_2]_2Cu$. Dashed curves are calculated from Kivelson's formulæ. a, Widths of $m_I = +\frac{1}{2}$ line; b, difference in widths between $m_I = -\frac{1}{2}$ and $m_I = +3/2$ lines. ×, 10^{-4} M; ○, 10^{-3} M

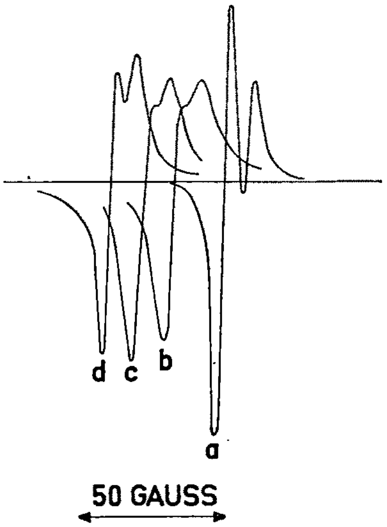

Fig. 2. $m_I = +3/2$ line of 10^{-3} M $[(C_2H_5)_2NCS_2]_2Cu$ in benzene–pyridine mixtures. The mole fraction of benzene is: a, 1·0; b, 0·9; c, 0·7; d, 0·0. Each line is an unresolved doublet due to the presence of two copper isotopes

Electron Spin Resonance Spectra of γ-Irradiated Carbohydrates and α-Hydroxy Acids

The production of polymers[1] from a wide range of carbohydrates and α-hydroxy acids induced by γ-irradiation of their de-aerated aqueous solutions posed the problem of identifying the monomer radicals responsible initially for such polymerizations. Measurement of the rates of dimerization of simple hydropyranols[2] and the polymer yields from some twenty model carbohydrates[3] suggested that, with glucose, one of the primary reactions involved was a dimerization of the radical derived by abstraction of a hydrogen atom from the carbon of the hydroxymethyl group. The identification[4] of the radical obtained on γ-irradiation of polycrystalline glycollic acid, using electron spin resonance spectra, and the presence of the same radical in the liquid phase, inferred from the isolation of tartaric acid[5] from irradiated, de-aerated aqueous solutions of glycollic acid, suggested a close correlation between these systems. Moreover, recent work[6] on single crystals has enabled the proton coupling tensor elements for protons in certain environments to be determined accurately. With glycollic acid the peak separation (~61 Mc./sec.) of the polycrystalline sample corresponded closely with the average value (57 Mc./sec.) of the H(C) coupling which represents the isotropic part of interaction.

The polycrystalline carbohydrate and α-hydroxy acid samples were sealed off in evacuated glass phials (5 mm. × 20 cm.) and irradiated from a 180 c. cobalt-60 γ-radiation source for 15 hr. at room temperature. The samples could be kept at liquid-air temperature, until their spectra were recorded at ambient temperature on an X-band reflexion spectrometer[7] using small magnetic field modulation and phase-sensitive detection to present the first derivative of the absorption on a pen recorder. The magnetic field was swept comparatively slowly, taking up to 15 min. to record the spectra. The results shown in Table 1 were interpreted on the basis of the work of Whiffen *et al.*[6] and McConnell *et al.*[8] on irradiated single crystals. The spectra of 1-deoxy and 2-deoxy D-glucose could not be resolved.

Table 1

Compound	Type of spectrum and peak separation	Radical postulated
D-Glucose	doublet 42 Mc./sec.	$-\dot{C}HOH$ (carbon 6)
D-Mannose	doublet 35 Mc./sec.	$-\dot{C}HOH$ (carbon 6)
L-Rhamnose	doublet 14 Mc./sec.	$>\dot{C}OH$ (carbon 1, 2, 3 or 4)
D-Arabinose	doublet 8 Mc./sec.	$>\dot{C}OH$ (carbon 1, 2, 3 or 4)
D-Glucal	quadruplet 44 Mc./sec.	$-CH=\dot{C}-$ (carbon 1 or 2)
Mandelic acid	multiplet ~ 10 Mc./sec.	$C_6H_5\dot{C}(OH)COOH$
Hexahydromandelic acid	singlet 0	$C_6H_{11}\dot{C}(OH)COOH$

The spectrum obtained from D-arabinose is only consistent with hydrogen ejection from carbons 1–4 since ejection from C_5 would give a doublet with a peak separation of about 40–50 Mc./sec.. L-Rhamnose appears to give a similar radical since a radical formed at C_6 of the type $\rangle\mathrm{C{-}CH_2}$ would give a triplet (relative intensities 1 : 2 : 1) of total splitting 100 Mc./sec. while ejection of a hydrogen at C_5 would be expected to give rise to a quadruplet (1 : 3 : 3 : 1) of total splitting about 210 Mc./sec. (compare results frim 2-methyl malonic acid, Pooley, D., and Whiffen, D. H., unpublished results). The peak separation and anisotropic broadening observed with irradiated glucose and mannose are consistent with hydrogen ejection at C_6, resembling as they do the spectrum of polycrystalline glycollic acid. The quadruplet spectrum (relative intensities 1 : 3 : 3 : 1) of D-glucal can only arise because of hydrogen ejection at C_1 or C_2 with subsequent delocalization of free spin in the π-bond orbitals and interaction with the three protons—two on C_3 and one on C_1 or C_2. This result is consistent with the radical inferred from the identification of stable end-products from irradiated aqueous solutions in which hydroxylation and fission of the double bond were the predominant effects. The singlet spectrum of hexahydromandelic acid would be expected from a radical obtained by hydrogen ejection at the asymmetric carbon atom since any other radical would exhibit considerable α- or β-proton couplings. In the case of mandelic acid itself, the spectrum was also consistent with hydrogen ejection from the asymmetric carbon atom and subsequent delocalization of free spin and coupling to the aromatic protons, and here the total splitting of about 90 Mc./sec. was similar to that observed[9] in aromatic radical ions. Ejection of an aromatic proton was very unlikely.

Although the above results were obtained with polycrystalline solids and as such should be treated with reserve, in all cases they are in agreement with the radicals, which have been inferred from the isolation of stable end-products in irradiated, de-aerated aqueous solutions of these compounds.

We wish to thank the United Kingdom Atomic Energy Authority, Research Division, Harwell, for supporting these investigations and for a maintenance grant to one of us (H. D. S.), and Prof. M. Stacey, for his interest in this work.

BIOPHYSICS

New Products from Wheat Starch, Flour and Gluten

Watson[1,2] has shown that graft polymers may be produced from certain substances of high molecular weight when they are masticated with monomers at ordinary temperatures in a machine in which high shearing forces are developed—the 'mechano-chemical reaction'. In the present work a laboratory machine of this type, invented by Watson[3], has been used to study the possibility of making, from different wheaten products, new substances of possible industrial importance.

In the first series of experiments, wheat starch or flour or gluten was masticated with a monomer, for example, styrene, methyl methacrylate, acrylonitrile or methacrylic acid, in the presence of glycerol. In all cases a product of hard, rubbery to rock-like, consistency was obtained, the type depending on the duration of mastication. In a typical example a mixture of 71 per cent starch, 16·5 per cent styrene and 12·5 per cent glycerol was masticated for 30 min., and from this powder a hard, dense product was obtained.

There is evidence from the present work that glycerol does not merely give a suitable consistency to the initial mixture for shearing but also it participates in the reaction. Thus, new products have been obtained by simply masticating starch and glycerol without the presence of a monomer. For example, 85 parts of starch and 15 parts of glycerol in the masticator for 20 min. gave a tough, rubbery product, which became harder as the time of mixing was increased. In the reaction with starch, glycerol may be replaced by various glycols, for example, ethylene glycol, or by glyceryl monoacetate. It cannot be replaced by mono-functional alcohols or by glyceryl diacetate. Similarly, wheat starch triacetate will not react with glycerol.

Compared with wheat starch, the products have a low solubility and high paste viscosity. The evidence suggests, therefore, that an essential step in the formation of these products from starch is the cross-linking of the starch chains by a bifunctional reagent. Furthermore, products are obtained by masticating wheat starch with either diethanolamine or formamide. The nitrogen contents of the products indicate that, if cross-linking has occurred, there is about one cross-link per six anhydroglucose units when diethanolamine is used and about one in three with formamide. By contrast, cross-linked starches prepared by conventional methods[4] usually have one cross-link per 50 or more anhydroglucose units.

Gluten (washed out of flour and freeze-dried) behaves differently from starch or flour. Masticated alone, it shows no obvious change; but with glycerol or glycerol and styrene it yields a hard product. On the other hand, unlike starch, it yields a similar product with glyceryl diacetate. By contrast, casein gives a hard product with glycerol but does not react with glyceryl diacetate.

The products from mastication of starch and flour with glycerol and monomers are practically insoluble in aqueous solutions and in the common organic solvents over a wide range of temperature. They have approximately the same vapour-pressure isotherm as the parent starch or flour. They can be hot-extruded to give fibres of a brittle character, with a breaking strength of 400–1,100 lb. per sq. in.

Full details of this work will be published elsewhere, including an account of further experiments to decide if, in some cases, the mechano-chemical effect is not predominant but activates a thermal reaction. Watson[5] has evidence that in certain cases this can occur.

BIOCHEMISTRY

Paper Chromatography of Hexosamines and N-Acetylhexosamines

An improved method of paper chromatography has been used to aid the separation of galactosamine hydrochloride from other hexosamine hydrochlorides in acid hydrolysates of chondroitin sulphate and to investigate the isomerization of N-acetylgalactosamine in alkaline conditions.

Barium chondroitin sulphate was prepared from dried bovine nasal cartilage by extraction with 1 *N* sodium hydroxide at 70° for 30 min. followed by neutralization and precipitation with 'Cetavlon'. Paper chromatography of fractions from 'Dowex-50' of hydrochloric acid hydrolysates showed the presence of glucosamine, galactosamine and an unknown amino-sugar. This amino-sugar was separated by re-elution from 'Dowex-50' with 0·3 *N* hydrochloric acid and identified as talosamine. Its hydrochloride was differentiated from galactosamine and mannosamine hydrochlorides and its N-acetyl derivative[1] from N-acetylglucosamine, N-acetylgalactosamine and N-acetylmannosamine by paper chromatography (Table 1) in butanol/pyridine/water (6 : 4 : 3). In the solvent of Fischer and Nebel[2] the mobility of the N-acetyl derivative relative to N-acetylglucosamine was 1·09, the same as that of synthetic N-acetyltalosamine[3].

Table 1. Paper Chromatography of Hexosamine Hydrochlorides and N-Acetylhexosamines

	Hydrochlorides		N-acetyl derivatives	
	A (cm.)	*B* (cm.)	*A* (cm.)	*B* (cm.)
Galactosamine	7·2	9·0	13·7	8·1
Glucosamine	8·1	10·9	14·9	10·4
Talosamine	7·9	11·5	16·1	13·3
Mannosamine	8·6	12·3	14·9	11·5
Solvent front	31·6	38·6	31·1	37·6

Solvent: Descending butan-1-ol/pyridine/water (6 : 4 : 3). Time, 16 hr.; temperature, 21°. Whatman No. 1 paper either (*A*) untreated or (*B*) with preliminary treatment in 0·1 *M* barium chloride. Sprayed for hexosamines and N-acetylhexosamines. Distances moved from origin (cm.).

Ninhydrin oxidation of the amino-sugar was carried out on the base-line of paper chromatograms[4], which were then developed in butanol/ethanol/water (4 : 1 : 1) or in butanol/pyridine/water and sprayed with benzidine–trichloracetic acid reagent. The derived pentose was neither arabinose nor ribose, but coincided with the lyxose/xylose position. A similar chromatogram, after development in butanol/pyridine/water for 19 hr., was sprayed with 0·05 *M* borate buffer, *p*H 9·6, and subjected to ionophoresis at right angles, using a current of 0·4 m.amp./cm. width for 20 hr. Pentose markers had the following ionophoretic mobilities: xylose, + 13·3 cm.; arabinose, + 10·5 cm.; ribose, + 9·5 cm.; lyxose, + 7·5 cm. The derived pentose (+ 7·7 cm.) was clearly lyxose and the original unknown amino-sugar (not galactosamine) was talosamine.

The separation of the amino-sugars and of their N-acetyl derivatives was improved by preliminary treatment of the paper with 0·1 *M* barium chloride (Table 1), due partly to faster solvent movement and partly to variations in R_F. We find this procedure preferable to that of Fischer and Nebel[2] for investigation of mixtures of these compounds. Borate-treated papers[1] give low R_F values for N-acetylhexosamines and N-acetylmannosamine coincides with N-acetylgalactosamine.

The isomerization of N-acetylglucosamine under alkaline conditions is known[5]. With 2 mgm. N-acetylgalactosamine and 0·125 ml. 1 per cent (w/v) potassium carbonate at room temperature for 2 days there was about 5 per cent conversion to a product corresponding to the previously identified N-acetyltalosamine. No further conversion was apparent after 4 days treatment.

N-acetyltalosamine was found to be present in a sample of N-acetylgalactosamine prepared by the acetylation of galactosamine hydrochloride derived from sheep tracheal cartilage[6].

These results do not necessarily mean that epimerization of N-acetylgalactosamine residues was responsible for the appearance of talosamine, because a high proportion of terminal residues would require to be epimerized during the alkaline extraction in order to give the talosamine (1 per cent of the total hexosamine) detected. If talosamine does occur naturally in cartilage, it may be associated with protein since purified chondroitin sulphate[7] contained no amino-sugar other than galactosamine and a neutral polysaccharide fraction[8] contained no amino-sugar other than glucosamine, but proof of its occurrence requires to be shown without use of alkali.

We are indebted to Prof. R. Kuhn and Dr. R. Brossmer for a gift of mannosamine hydrochloride.

Catalysis of Metalloporphyrin Formation: a Possible Enzyme Model for Hæm Iron Incorporation

RECENT investigations on the incorporation of metal ions into porphyrins solubilized in aqueous detergent solutions have revealed two factors having a marked influence on the reaction-rate. The first is related to the charge on the detergent and has been termed the electrostatic effect; the second is concerned with the presence of certain chelating agents, and has been termed the co-ordination effect.

The electrostatic effect is such that the rate of incorporation of cupric ions (Cu^{++}) into dimethyl protoporphyrin ester is 20,000 times faster in 2·5 per cent sodium dodecyl sulphate than in 5 per cent cetyl trimethylammonium bromide under otherwise comparable conditions. This effect can be attributed to the electrostatic attraction of the cupric ions to the anionic micelle–water interface, where presumably they are able to interact with the nitrogen atoms in the tetrapyrrole nucleus. A possible structure for the solubilized porphyrin in which the pyrrole nitrogens are exposed to the aqueous phase is shown in Fig. 1.

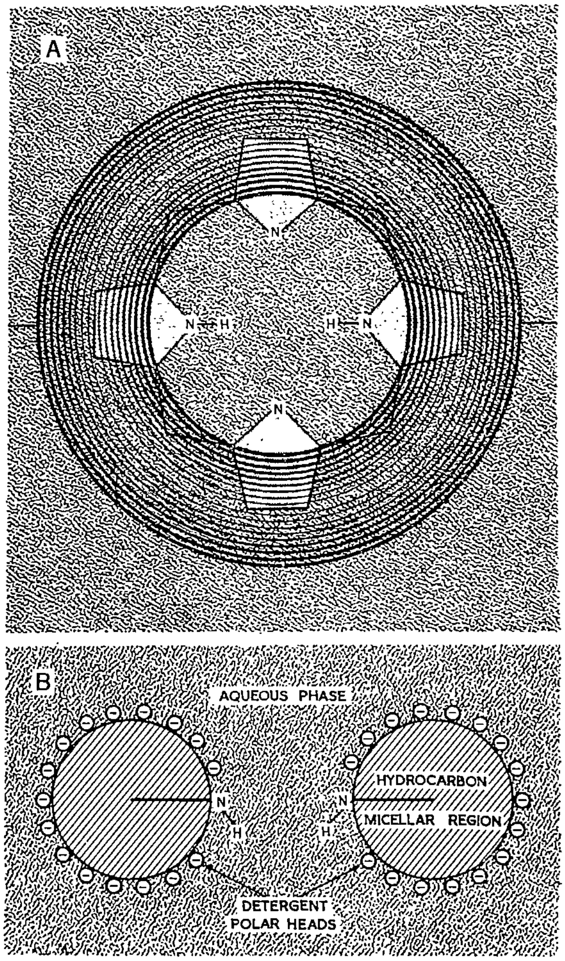

Fig. 1. A possible structure for the porphyrin – micelle complex with the porphyrin mainly immersed in the hydrocarbon region of the micelle and the nitrogen atoms in contact with the aqueous phase. *A*, plan; *B*, sectional view

The co-ordination factor is illustrated in Fig. 2, which shows the effect of increasing concentrations of 8-hydroxyquinoline (OX) on the initial rate of formation of copper protoporphyrin ester in a 2·5 per cent sodium dodecyl sulphate solution. It will be noted that the effect is maximal when the mole ratio of cupric ions to 8-hydroxyquinoline is 1 : 1, and that at higher concentrations of 8-hydroxyquinoline the rate is depressed. This suggests that the 1 : 1 $[Cu\ OX]^+$ complex is the active catalytic species. A similar effect has been observed in cationic and non-ionic detergent solutions. Because of the interplay of electrostatic and co-ordination factors in practice (one must, for example, compare the divalent cupric ion with the monovalent $[Cu\ OX]^+$ ion) it is difficult to assess the absolute catalytic effect of the co-ordination factor. However, it can be estimated to be 200–2,000-fold. The effect of other chelating and co-ordinating agents on the reaction-rate will be discussed in a further communication.

The temperature coefficient of the reaction ($Q_{10}\sim 2$) is unaffected by the presence of catalytically

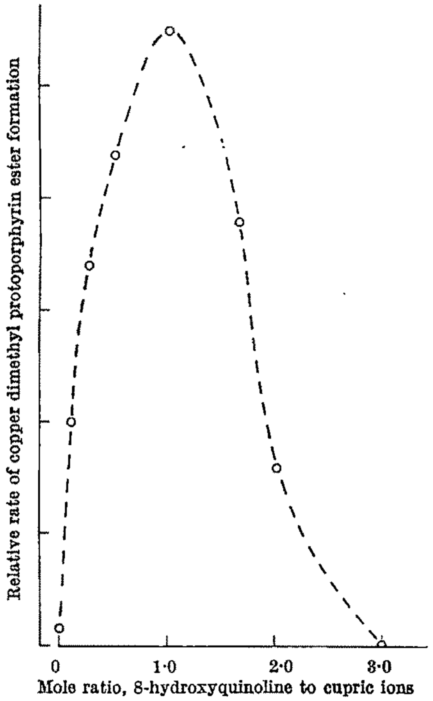

Fig. 2. Effect of varying the concentration of 8-hydroxyquinoline on the initial rate of formation of copper dimethyl protoporphyrin ester in 2·5 per cent sodium dodecyl sulphate at 40° C. The initial concentrations of cupric ions and dimethyl protoporphyrin ester were constant at $10^{-5} M$ and $10^{-6} M$ respectively. The pH was ~ 7·0

active $[Cu\ OX]^+$ species. This suggests that the co-ordination effect influences the probability of an effective collision (that is, the activation entropy) rather than the activation energy.

The maximum increase in rate yet observed from the combined influence of the electrostatic and co-ordination effects is 500,000-fold. This corresponds to the difference in initial reaction-rates between $[Cu\ OX]^+$ and dimethyl protoporphyrin ester in 2·5 per cent sodium dodecyl sulphate and cupric ions and dimethyl protoporphyrin ester in 5 per cent cetyl trimethylammonium bromide at comparable temperatures. Both effects have been observed to influence the rate of incorporation of ions other than cupric ions, for example, cobalt, nickel, ferrous iron and zinc.

The reaction studied in this system has features in common with an enzyme-catalysed reaction. Thus, the detergent solution, which consists of lipoidal micellar regions dispersed throughout an essentially aqueous phase, resembles the colloidal nature of the biological environment. The role of the detergent micelle in reacting with one of the substrates dimethyl protoporphyrin ester and simultaneously attracting the other substrate (cupric ions) to the same vicinity parallels the behaviour of an enzyme in bringing the reactants together—the porphyrin–micelle complex being analogous to an enzyme–substrate complex. The 8-hydroxyquinoline might be regarded as a co-factor which, by co-ordinating with one of the substrates (cupric ions) thereby facilitates the reaction. Both the electrostatic and co-ordination effects arise from changes in the entropy rather than the energy of activation, the electrostatic effect being associated with a concentration entropy term and the co-ordination effect with an orientation entropy term.

It is interesting to note that the large catalytic effect observed in this system has arisen solely from favourable changes in the entropy of activation. The importance of the entropy of activation in enzymic reactions has recently been pointed out[1] in connexion with the role of magnesium ions in enzyme syntheses involving adenosine triphosphate.

This hypothesis might have some relevance to the incorporation of iron in the biosynthetic formation of hæm. Preliminary experiments have indicated that the rate of incorporation of ferrous ions into porphyrins in this system is several hundred-fold greater than that observed in other aqueous systems[2–4], although still considerably less than the known enzymic rate[5–7]. However, the relative magnitude of the effects discussed here is such that the enzymic rate of incorporation might yet be equalled by a further chemical modification of the system.

Gastro-Intestinal Absorption of Heparin and Synthetic Heparinoids

Heparin and synthetic heparinoids have to be administered parenterally to assure clinical efficacy[1]. Since oral administration of these drugs would be highly desirable, numerous compounds were tested for their ability to effect absorption from the gastro-intestinal tract. The criterion of absorption was the appearance of plasma lipæmia-clearing activity, which was first described by Hahn[2].

Several compounds ('adjuvants') were discovered to have this property, the best of these being certain salts of ethylenediaminetetraacetic acid (EDTA). Other active compounds will be the subject of future communications. The present communication describes the use of salts of EDTA to obtain absorption of heparin and synthetic heparinoids.

Rats weighing about 200 gm. were placed in individual cages and fed for 72 hr. a liquid diet consisting of 30 ml. of a 33 per cent casein hydrolysate and water *ad lib.* The drug was given by intubation of an aqueous solution at a volume of 10 ml./kgm.

Table 1. Rat and Dog Lipæmia-Clearing Activity 4 hr. after Oral Sulphopolyglucin plus EDTA

Animal	No. of animals	SPG (mgm./kgm.)	Sodium salt of EDTA (mgm./kgm.)	Lipæmia-clearing activity (C.U.*)
Rats	5	500	—	0·04 ± 0·03
	5	500	500	2·41 ± 0·74
	4	—	500	0·01 ± 0·01
Dogs	5	100	—	0·59 ± 0·41
	6	100	50	5·73 ± 1·04

* Mean ± standard deviation

Table 2. Lipæmia-clearing Activity and Clotting Time after Oral Heparin plus EDTA in Rats and Dogs

Rats			Dogs		
Heparin 50 mgm./kgm. Sodium salt of EDTA 500 mgm./kgm.			Heparin 100 mgm./kgm. Sodium salt of EDTA 50 mgm./kgm.		
Time (min.)	Clearing activity (C.U.*)	Clotting time (min.)	Time (hr.)	Clearing activity (C.U.*)	Clotting time (min.)
0	0·04 ± 0·03 (5)	7·0 ± 1·7 (16)	0	0·19 ± 0·18 (4)	11·3 ± 2·1 (8)
10	0·10 ± 0·09 (3)	11·0 ± 1·3 (3)	1	0·85 ± 0·70 (4)	>28 ± 21 (8)
30	1·46 ± 0·17 (3)	13·3 (2)	2	0·99 ± 0·66 (4)	>44 ± 22 (8)
60	0·31 ± 0·24 (3)	8·0 (1)	4	0·31 ± 0·45 (4)	18·1 ± 8·2 (8)

Figures in parentheses are number of animals. >, some animals had incoagulable blood (> 60 min.). *, Mean ± standard deviation.

At specified times, the rats were anæsthetized with pentobarbital sodium, and blood samples taken by cardiac puncture.

In dogs, after an overnight fast, the drugs were given orally in gelatin capsules. Blood samples were taken by venipuncture at specified intervals. Lipæmia-clearing activity of citrated plasma was determined[3] and expressed in clearing units (C.U.) calculated according to Grossman, except that incubation time was limited to 10 min., and the substrate was 'Ediol' (SchenLabs), diluted 1 to 50 with water. Whole-blood clotting time was determined by a three-tube Lee–White method[4] and indicated in minutes. When blood did not clot within 60 min., a value of 60 min. was used in calculating mean clotting time, but the '>' sign was added. All values for clearing activity and clotting time are given as mean ± standard deviation for groups of 5–10 animals or as specified.

The drugs used were heparin sodium U.S.P., potassium salt of sulphopolyglucin (SPG) and various salts of EDTA. SPG is a sulphated polysaccharide of 5 to 15 glucose units connected by α,1–4, and α,1–6 linkages, with 2–3 sulphate groups per glucose unit.

Typical experiments demonstrating the adjuvant property of sodium EDTA are presented in Table 1. Using lipæmia-clearing activity as an index of absorption, the results show, without question, the adjuvant properties of sodium EDTA. In dogs, where SPG alone produces measurable although somewhat erratic clearing activity, absorption of the heparinoid is increased about ten-fold by simultaneous administration of the sodium salt of EDTA. In rats, the effect of EDTA is even greater, since SPG alone is practically not absorbed.

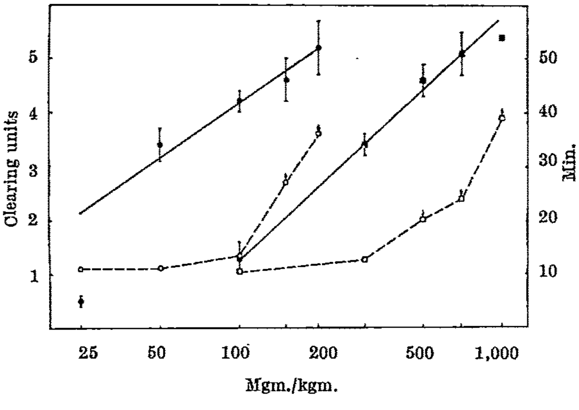

Fig. 1. Dose-response curves for lipæmia-clearing and anti-coagulant activities of SPG without and with EDTA in a ratio 4 : 1. Drugs given orally to groups of 5–10 dogs and blood taken 3 hr. later. Arrows indicate clotting times of more than 60 min. in some specimens. Limits in lipæmia-clearing curves are standard error. ● ○, EDTA; ■ □, no EDTA; —, clearing; – – –, clotting

Similar results with SPG have been found in every animal species studied (monkey, dog, cat, rabbit and rat), as well as in man[5]. The adjuvant property of EDTA has also been demonstrated for other synthetic heparinoids (polyethylene sulphonate, dextran sulphate and others).

The adjuvant property of the sodium salt of EDTA can also be demonstrated for heparin, using both clotting time and clearing activity as criteria of absorption (Table 2).

The effects of EDTA are again unequivocal. In rats, clearing activity reached a peak about 30 min. after administration of the drug combination, and then declined slowly to control-levels. A similar time course was obtained for the anti-coagulant effect, with doubling of the clotting time at about 30 min. after the drug and subsequent return to control-levels. Since it is known that heparin is not absorbed from the gastro-intestinal tract, control experiments without EDTA were not made.

In dogs, the typical heparin effects appeared slower than in the rats. The peak of clearing activity and anti-coagulant effects were reached about 2 hr. after drug combination and returned to control-levels after more than 4 hr.

Further experiments were carried out in dogs to establish dose-response curves for SPG, both with and without EDTA. The results in Fig. 1 show good correlation between dose and clearing as well as anti-coagulant activity. Statistical evaluation indicated that the efficacy of SPG was increased approximately five-fold when EDTA, in the ratio 1 : 4, was used as adjuvant.

Significant amounts of heparin and synthetic heparinoids can be absorbed from the gastro-intestinal tract when these drugs are given orally together with an alkali salt of EDTA. The mechanism of this adjuvant effect is not clear. There is evidence that the chelation of calcium and/or magnesium ions by EDTA may be involved for the following reasons: (1) Sodium, potassium and ammonium salts of EDTA are effective as adjuvants; (2) calcium and magnesium EDTA are not effective; (3) adding a calcium salt blocks the adjuvant action of alkali EDTA; (4) phosphate buffers are not effective; (5) the adjuvant has to be given orally; intravenous injection of the adjuvant does not influence the absorption of SPG from the gastro-intestinal tract.

Changes of Hexose/Hexosamine Ratio and Degree of Branching in Glycoprotein from Rat Urine during the Development of Cancer

We have isolated, from the urine of patients with cancer, an abnormal glycoprotein (III)[1] from fraction II (richest in carbohydrate, but low in sialic acid) of the Anderson–MacLagan glycoprotein (I)[2], which was characterized by a decreased hexose/hexosamine ratio, increased oligosaccharide-branching due to hexosamine and L-fucose residue and increased molecular weight, as compared with the exactly corresponding glycoprotein of urine of non-cancerous origin[1] (IV). These changes were observed, however, on fractions III and IV prepared from urine of patients with different stages of cancer, and also from normal and non-cancerous subjects[1]. We wished, therefore, to study those changes under comparable conditions, such as experimental cancer or inflammation, so as to follow up changes during pathological processes. But technical difficulties were great, since the yield of III is only 2–3 per cent by weight of I, and we were limited by the small quantity of animal urine available. It was observed, however, that the characteristic changes can be recognized even at the stage of purity of substance II.

Urine of four groups of ten rats (Wistar strain, female) were collected under toluene. The rats were inoculated intraperitoneally with ascites hepatoma 136 (Sasaki Institute, Tokyo), and afterwards pooled urine was separated every four days and substance II glycoprotein fractions were prepared; substance I from the pooled rat urine was solubilized with water at *p*H 8·4 (insoluble part rejected) and precipitated at *p*H 4·2, and centrifuged. The supernatant was electrodialysed for 3 days to effect complete precipitation, and the supernatant was lyophilized and analysed without further purification. In two groups of ten rats, inflammation was set up by intraperitoneal injection of turpentine oil, and the urine of days 2–7 after injection were taken, similarly treated and analysed.

Table 1. CHANGES OF GLYCOPROTEIN FRACTION II IN INFLAMMATION AND DURING DEVELOPMENT OF CANCER

	Normal rats (before inoculation)	Inflammatory rats† (turpentine peritonitis)	Cancer-bearing rats* (ascites hepatoma 136, Sasaki)			
			Days after inoculation

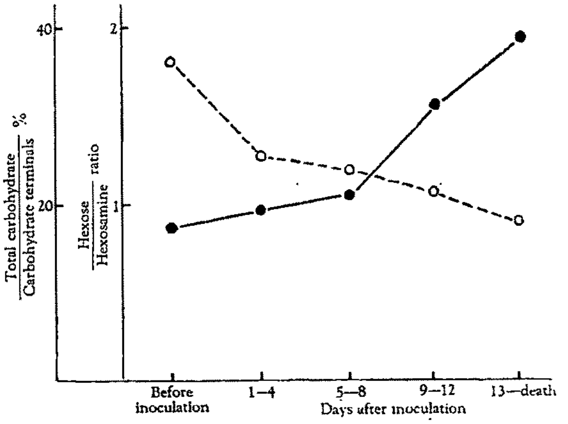

Fig. 1. Changes of degree of branching (full line) and ratio of hexose to hexosamine (dotted line) of the glycoprotein II from rats during development of cancer

As is shown in Table 1 and Fig. 1, the non-amino- to amino-sugar ratio decreased, and the ratio of the total carbohydrate to end-group carbohydrate increased with the development of cancer, but these ratios remained unchanged in the case of inflammation.

In view of the significant role of oligosaccharide branching and the hexose/hexosamine ratio in the determination of the biological specificity of mucosubstances[7], it is considered that the lost hexoses and increased branching observed in the abnormal glycoprotein must reflect lost specificity of the normal molecule, and leads to the appearance of the structure responsible for pathological specificity.

Fractionation of Compound Lipids by Dialysation in an Organic Solvent against an Organic Solvent

Compound lipids in general are not dialysable in aqueous solution or emulsion because they form micelles. Their dialysability in organic solvents, however, has not been examined in detail; but it seems to be largely dependent on the state of the organo-micelle[1]. It was therefore thought that by dialysation of individual compound lipids in organic solvents against successive changes of solvents of different polarity, the so-called 'high-molecular lipids'[5] or 'mucolipids'[2,3] would remain undialysable if they are really of high molecular weight.

We have examined the dialysability of various compound lipids in a number of organic solvents, and the following findings are of special interest: (1) Chol-

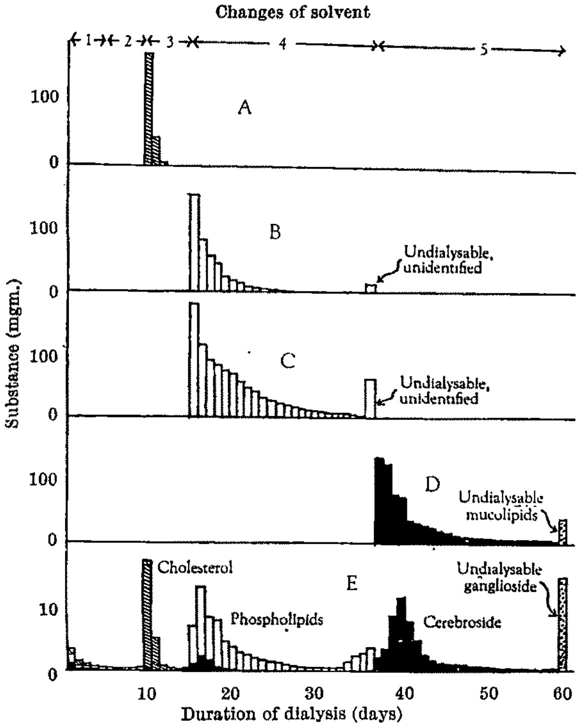

Fig. 1. Dialysability of cholesterol (*A*) in chloroform; I (*B*); mixture of II and III (*C*) in chloroform–methanol (2 : 1 v/v); IV (*D*) in pyridine and of a mixture of these with V (*E*). Dialysis was carried out by using a Visking tube, 1 cm. × 20 cm. against a 100-ml. aliquot of various solvents. Solvent 1 : benzene/petroleum ether (1 : 1, v/v). Solvent 2 : benzene/chloroform (1 : 1, v/v). Solvent 3 : chloroform. Solvent 4 : chloroform/methanol (2 : 1, v/v). Solvent 5 : pyridine. Temperature, 5 ± 1. The abscissa represents the duration of dialysis in days and the ordinate is the amount of substance dialysed in mgm. In experiment (*E*), 20–50 mgm. each of the mixed material dissolved in 80 ml. of benzene petroleum ether (1 : 1) placed in a 1 cm. × 40 cm. Visking tube were dialysed in 100 ml. of solvent

esterol, phosphatidyl-cholin (I), -ethanol amine (II) and -serine (III), and cerebroside (IV) can be dialysed in different polarity of the media used through Visking 24 Å. membrane (see Fig. 1). A trace of undialysable portion was recognized in substances I–IV, even in chromatographically pure substances I–III (ref. 4), but the undialysable remainders of I–III have not been identified as yet. Ganglioside (V) prepared from strandin[5] fraction cannot be dialysed in any of the media.

(2) Substance IV, prepared from protagon[6], crystallized thrice from ethanol, twice from glacial acetic acid, can be separated into a dialysable fraction (VI) and an undialysable fraction (VII) by dialysation for two weeks in pyridine (outside liquid changed every day). Substance VII was separated into water-soluble supernatant (VIII) and gelatinous precipitate (IX) when dialysed against water (150 mgm. of VIII and 230 mgm. of IX from 6·5 gm. of IV).

The fast dialysable (within 2–3 days) fraction of (V) was identified as almost pure cerebroside by analysis ; N, 1·70; hexose, 18; P, 0·01; SO_4, 0·2 per cent; $[\alpha]_D^{25}$ in pyridine, 4·5°. The hydrolysate gave only galactose (a typical infra-red spectrum). The slowly dialysable (7–14 days) fraction of (V) contains mainly galactose and also a small amount of galactosamine, but no glucose.

From substance VIII was isolated by chromatography on cellulose[7], two main peaks eluated with methanol/chloroform/water (7 : 3 : 0·5 by vol.). They were typical of mucolipids but different from ganglioside[8] or 'brain mucolipid'[3]; they were characterized by strong dextro-rotation, ($[\alpha]_D^{18}$ in pyridine = +68° and +84° respectively), but both contain glucose, galactose, galactosamine and a trace of sialic acid. Substance IX has not yet been purified, but is believed to be a glycolipid linked with polypeptide (the hydrolysate gave such amino-acids as glutamic acid, aspartic acid, serine, glycine, leucine and valine); N, 3·5 per cent; hexose, 25; P, 0·8; sialic acid, 5·5 per cent. It is noticeable that only the undialysable fractions (VII and VIII) contain a considerable amount of glucose.

(3) Fractional dialysation of artificial mixtures of cholesterol, I, II, III, IV and V has been tried. Although up to the present simultaneous dialysation (co-diffusion) of a small amount of IV with the majority of II and III has been observed, almost successful separation of individual compound lipids has been accomplished, as is shown in Fig. 1*E*. Substance V, which is thought to be the only high-molecular lipid among these mixtures, has been recovered as the undialysable remainder.

This type of fractionation may be of considerable importance, since it does not include any drastic treatment and can resolve the individual lipids in their native state.

Full characterization of the individual fractions will appear in detail elsewhere.

Fractions of Trypsinized Casein giving Different Patterns of Bacterial Growth

THE rate of growth of a strain of *Streptococcus equisimilis* in a medium comprising acid-hydrolysed casein, glucose and yeast extract has been shown in these Laboratories to be markedly increased by the addition of a small amount of a tryptic digest of casein. While investigating this effect, which had been shown not to be due to the ability of the enzymic digest to supply free amino-acids, it was found to be possible by chromatography on paper in *n*-butanol/acetic acid/water (25 : 6 : 25 by vol.) to fractionate the digest in such a way as to separate compounds possessing growth-stimulating activity of two distinct types. Thus constituents of the digest possessing approximately the same R_F as that of glycine resulted, after a very short lag, in a sudden increase in the rate of growth of the organisms which, however, was of short duration (Fig. 1*a*). On the other hand, the effect of constituents of the digest with R_F values similar to that of valine reached a maximum only after a prolonged lag and differed again from the previous effect in that the high rate of growth was sustained (Fig. 1*b*).

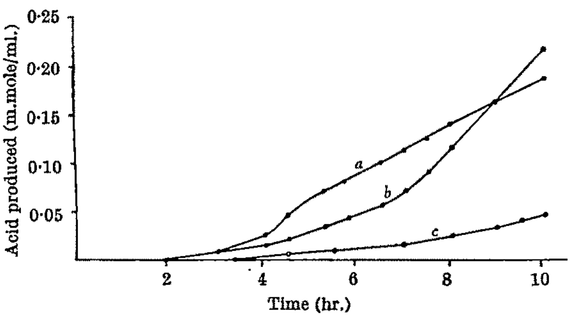

Fig. 1. Growth patterns of a strain of *Streptococcus equisimilis* showing effect of fractions of trypsinized casein separated chromatographically. For convenience, growth is expressed as m.mole/ml. of lactic acid produced. *a*, Basal medium + glycine fraction ; *b*, basal medium + valine fraction ; *c*, basal medium

It seemed almost certain from the protein nature of the starting material that the active substances in the casein digest were peptides, and indeed, an active peptide with the same R_F value as that of valine has now been isolated chromatographically from a tryptic digest of casein. The effect of this peptide was of the predicted type, as rapid growth-stimulation occurred only after a long lag period. Fractions obtained by filtration of casein digests through 'Sephadex *G*-25' (ref. 1) were further resolved by a two-dimensional technique involving the successive use of paper chromatography and high-voltage electrophoresis[2]. By these means, the presence has been confirmed of a great multiplicity of peptides in both the glycine and valine regions of chromatograms (Fig. 2).

It has been known for some time that certain natural or synthetic peptides exert a stimulatory effect on micro-organisms, particularly the *Lactobacilli*[3], while more recently, Kihara and Snell[4] have advanced the attractive theory that this stimulatory effect resides in the ability of peptides in some instances to overcome blocks in the metabolism of individual amino-acids.

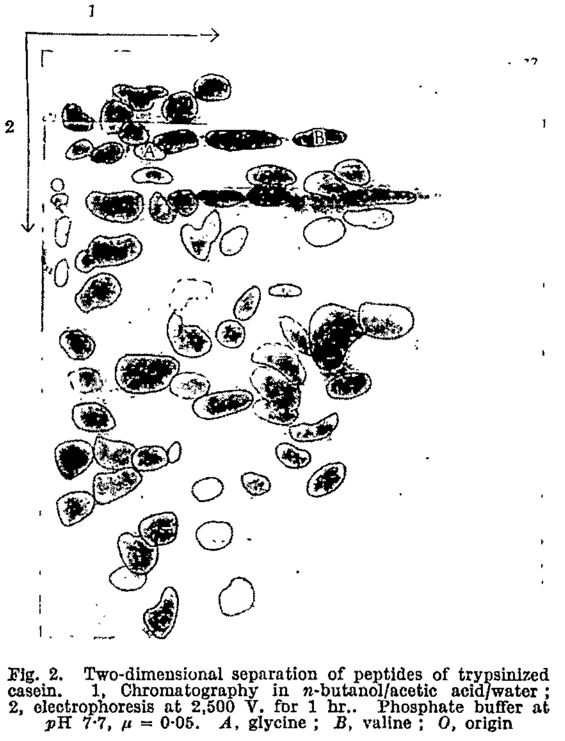

Fig. 2. Two-dimensional separation of peptides of trypsinized casein. 1, Chromatography in *n*-butanol/acetic acid/water ; 2, electrophoresis at 2,500 V. for 1 hr.. Phosphate buffer at *p*H 7·7, μ = 0·05. *A*, glycine ; *B*, valine ; *O*, origin

In the present work the diverse effects shown by the two peptide fractions might be interpreted as indicating the changing requirements of the bacterium for specific peptides at different stages of growth. On the other hand, it is possible that the present results relate to current theory as follows : Pattern 1*a* may represent the effect of a group of peptides which help the organism to overcome metabolic blocks but which, through being present in submiminal amounts, fail to show sustained activity. Pattern 1*b* may represent the effect of a group of peptides which are not of themselves active but which give rise to active substances as a result of structural modifications arising through the action of enzymes produced by the bacterium. The long lag may then be regarded as the period required for the synthesis or action of the appropriate enzyme system. Alternatively, the lag may represent the interval necessary for the micro-organism to elaborate the system for transporting the peptides across the cell wall. These and other related problems are at present under investigation.

Biosynthesis of Choline *in vitro* by Rat Liver

In conformity with the observation that only one of the three methyl groups of choline, after oxidation to betaine, can be transferred to homocysteine[1], it was shown from *in vivo* studies[2] that only the conversion of dimethylethanolamine to choline is a transmethylation, the influence of folic acid being confined to steps leading to the formation of monomethylethanolamine and dimethylethanolamine from ethanolamine. The present *in vitro* experiments were carried out to ascertain, more directly, the origin of the methyl groups of choline, and their relationship to folic acid.

Since homogenation resulted in complete loss of ability to form choline[3], several rat liver slices were incubated, separately, with ethanolamine, monomethylethanolamine and dimethylethanolamine in presence of (3-^{14}C) serine or (Me-^{14}C) methionine. The involvement of folic acid in one or more of the methylations in choline biosynthesis from ethanolamine, can be inferred from the significantly lower incorporation of activity into phosphatidyl choline by liver slices of folic acid-deficient rats as compared with those of the folic acid-supplemented controls, except when dimethylethanolamine and (Me-^{14}C) methionine were incubated together (Table 1). This lack of effect in the latter case would suggest that the methylation of dimethylethanolamine is predominantly a transmethylation. On the other hand, the appreciable amounts of activity incorporated from the methyl group of methionine into phosphatidyl choline in presence of ethanolamine and monomethylethanolamine, even in folic acid deficiency (Table 1).

Table 1. Folic Acid Deficiency and Incorporation of (Me-^{14}C)-Methionine and (3-^{14}C)Serine into Phosphatidyl Choline

Additions	(Me-^{14}C)methionine		(3-^{14}C)serine	
	+ Folic acid	− Folic acid	+ Folic acid	− Folic acid
	Total counts/min./vessel in phosphatidyl choline *			
Ethanolamine	1,452	502	1,043	268
Monomethylethanolamine	1,133	392	616	115
Dimethylethanolamine	1,918	1,486	906	172

* Average values for five independent incubations.

Each incubation vessel contained 500 mgm. of normal or folic acid deficient (ref. 4) rat liver slices in 5 ml. Krebs–Ringer phosphate buffer *p*H 7·4, containing 3×10^{-4} *M* (Me-^{14}C)methionine or (3-^{14}C)-serine and $3 \cdot 8 \times 10^{-4}$ *M* either ethanolamine, mono- or dimethyl-ethanolamine. Incubations were performed in air for 2 hr. at 37° C. The reaction was stopped by addition of 2 ml. of a 3 : 1 mixture of ethyl alcohol–ethyl ether. Extraction of phospholipids, hydrolysis and separation of choline were according to Pilgeram *et al.*, ref. 3.

would indicate that transmethylation is also involved in providing methyl groups for dimethylethanolamine synthesis. The methyl groups of choline, therefore, seem to be derived by transmethylation as well as folic acid-dependent reactions, the latter being predominant with the first two steps and the former with the last one. These observations are in keeping with recent findings of Venkataraman and Greenberg[5], who have defined an active soluble enzyme system in liver, capable of synthesizing all the choline methyl groups from formaldehyde, tetrahydropteroylglutamic acid serving as a co-factor, and of Bremer and Greenberg[6], who have shown that rat liver microsomes could synthesize monomethylethanolamine and dimethylethanolamine, as well as choline, by transmethylation.

There is a graded decrease in the activity of phosphatidyl choline formed in presence of ethanolamine and monomethylethanolamine, possibly because, on an equimolar and random basis, for every ethanolamine and monomethylethanolamine molecule, there will be 3 and 2 methyl groups respectively entering. The rate-limiting nature of earlier methylations[6] would explain the higher incorporation with dimethylethanolamine (Table 1).

Experiments in Table 2 serve to show that the observed folic acid-dependent incorporation of the β-C of serine into phosphatidyl choline, synthesized from dimethylethanolamine (Table 1) probably occurs through prior conversion to the methyl moiety of methionine[8]. The β-C of serine is incorporated more extensively into methionine than into choline of the acid-soluble fraction. The incorporation reaches a maximum in 0·5 hr., while it increases steadily for 2 hr. in phosphatidyl choline. Arnstein and Neuberger[9] have also indicated from *in vivo* work that methionine synthesis precedes choline synthesis, the hydroxymethyl group of serine being an important precursor of the methyl group of methionine.

Table 2. Relative Rates for Incorporation of (3-^{14}C)Serine into Acid-soluble Methionine, Choline and Phosphatidyl Choline

Incubation time (hr.)	Acid-soluble fraction				Phosphatidyl choline	
	Methionine		Choline			
	A	*B*	*A*	*B*	*A*	*B*
	Total counts/min./vessel*					
0	489	450	234	228	0	0
½	18,237	5,408	1,736	2,440	381	478
1	13,469	15,016	913	1,902	927	1,202
2	10,263	14,720	551	1,608	1,228	1,287
3	8,998	10,124	378	750	1,278	1,306

* Average values for five different incubations.

Each reaction vessel contained 400 mgm. rat liver slices in 5 ml. of Krebs–Ringer phosphate buffer, *p*H 7·4, containing 3×10^{-4} *M* (3-^{14}C)serine and $3 \cdot 8 \times 10^{-4}$ *M* each of ethanolamine and homocysteine in experiments *A* and dimethylethanolamine and homocysteine in experiments *B*. Incubations were performed in air at 37° C. The reactions were stopped at different time intervals by adding trichloracetic acid (5 per cent). Choline, methionine and serine were added, each at 1-mgm. level, as carrier and the amino-acids separated essentially according to the method of Moore and Stein (ref. 7). Choline was eluted finally by 1·5 *N* hydrochloric acid. Phosphatidyl choline was isolated as explained in legend for Table 1.

This investigation is being extended with the sub-fractions of the cell.

Reaction of Digitalis Compounds with Antimony Pentachloride

Antimony pentachloride has been used as an agent for the detection of steroids in paper chromatography by a number of investigators[1–4]. It has been found that antimony pentachloride is a useful agent for detecting certain digitalis compounds (digoxin, digitoxin and digitoxigenin) on paper chromatograms.

Crystalline digitoxin and digitoxigenin (obtained from Nutritional Biochemicals Corp., Cleveland, Ohio) in chloroform and crystalline digoxin (obtained from Burroughs Wellcome and Co., Inc., Tuckahoe, New York) in a 1 : 1 solution of 95 per cent ethanol and chloroform were placed on a 0·8 cm.^{2} area on Whatman No. 7 paper in varying amounts. Antimony pentachloride in chloroform (20 gm. in 100 ml.) was sprayed on the paper. An immediate reaction occurred. All three compounds became yellow in colour and the digoxin and digitoxin quickly took on an intense purple colour. The digitoxigenin slowly took on a green colour at the 50- and 25-μgm. level, but remained yellow with lesser amounts.

Table 1. Reaction of Digitalis Compounds with Antimony Pentachloride

Compound	Colour before heating	Minimum amount detectable (μgm.)	Colour after heating	Minimum amount detectable (μgm.)
Digoxin	Purple	1·0	Black	0·5
Digitoxin	Purple	1·0	Black	0·5
Digitoxigenin	Green or yellow	1·0	Darker green or yellow	0·5

After heating the sprayed paper at 84° C. for 5–10 min. the digoxin and digitoxin became intensely black, while the digitoxigenin turned a darker shade of green or yellow.

Table 1 shows the changes in colour before and after heating and the least amount detectable. After heating the compounds were much more easily visible at the 1·0–5·0 μgm. range than before heating.

RADIOBIOLOGY

A General Method for the Quantitation of Immune Cytolysis

THE cytolytic effect of immune serum has been the subject of study by a number of investigators. It has been shown[1] that cells other than erythrocytes undergo lytic changes in the presence of antibody and complement. It has been further shown[2], using cells labelled with phosphorus-32, that the lysis of such cells is accompanied by a release of intracellular proteins, similar to the release of hæmoglobin from lysed erythrocytes. It appeared that the immune lysis of tissue cells is quite analogous to the immune lysis of erythrocytes. On this basis, a test was developed using radioactive labelled cells which provides a means of quantitating immune lysis for cells derived from a variety of tissues.

Mouse Ehrlich ascites tumour cells grown in *CF* No. 1 female mice and the corresponding immune rabbit serum were used for the demonstration of this method. The tumour cells were collected from the peritoneal cavity of the mouse, washed 3–5 times by centrifugation and decantation with a diluent composed of veronal buffered saline, *p*H 7·4 (ref. 3), containing 1 per cent bovine albumin (Armour Laboratory, Kankakee, Illinois). The washed tumour cells were labelled with 50 μc. of chromium-51 ('Ra-chromate', Abbott Laboratory, North Chicago) per ml. packed tumour cells. After an incubation period of 1 hr. at room temperature, the labelled cells were washed five times with diluent. An uptake of 60–70 per cent of the radioactivity was obtained. The cell concentration was then adjusted to 1 per cent on the basis of either packed cell volume or cell count. It was found that a 1 per cent suspension corresponding to 4 × 10^6 cells/ml. was optimal for these tests. It was also found that only those cells were suitable which had been collected and labelled on the same day the test was performed.

The total volume of the cytolytic test was 3·0 ml., consisting of 1·0 ml. serum dilution, 1·0 ml. complement dilution (lyophilized guinea pig serum, Sharp and Dohme, Philadelphia) and 1·0 ml. of the chromium-51-labelled cell suspension. (A protocol for a typical antibody cytolytic titration is given in Table 1.) The test was incubated for 1 hr. at 37° C. and centrifuged. Then the clear supernatant fluids were gently removed by aspiration. Finally, 1·0-ml. aliquots of the supernatant liquids were counted for radioactivity. The values obtained (antibody or complement titration) were corrected for non-specific loss of radioactivity from the cells (tube 7*c* of Table 1) and then the percentage of specific lysis was calculated by dividing the corrected counts by the number of counts corresponding to 100 per cent lysis.

In order to obtain a 100 per cent value for cell lysis, it was necessary, because insoluble as well as soluble components of the cell had been labelled, to determine the amount of radioactivity associated with the soluble components only. Ultrasonic vibration was considered to be the most suitable method for cell disruption; therefore, an aliquot of the labelled cell suspension was sonated for 15 min. (magnetostriction oscillator, model *S*-102*A*, Raytheon Mfg. Co., Waltham, Mass.) and the lysed cell suspension centrifuged for 1 hr. at 16,000*g*. The clear supernatant fluid was diluted 1 : 3, and a 1·0-ml. aliquot used for counting. The counts were corrected for non-specific loss of radioactivity and were used as the value for 100 per cent lysis. This value agreed well with the number of counts found when excess complement and antibody were used to obtain maximum lysis. The values for 100 per cent lysis varied between 71 and 76 per cent of the corrected total radioactivity present.

All further treatment of the data was the same as that described by Kabat and Mayer[4] for the determination of hæmolysin titre in terms of 50 per cent hæmolytic units. The values obtained for percentage lysis (Y) of different amounts of serum or complement were converted to $Y/(1-Y)$ values and the amount of serum versus the corresponding $Y/(1-Y)$ values was plotted on logarithmic paper. The amount of serum required for 50 per cent lysis was estimated from the graph (where $Y/(1-Y) = 1{\cdot}0$). Repeated titrations of the same serum, carried out on different days, were found to agree within 5 per cent.

Table 1. TYPICAL PROTOCOL FOR THE QUANTITATION OF ANTIBODY CYTOLYTIC ACTIVITY

Tube No.	Ml. serum*	Ml. diluent (alb.-V.B.)	Ml. complement (four 50 per cent units)	Ml. 1 per cent cells (^{51}Cr labelled)	Counts/min./1·0 ml. aliquot supernatant	Corrected counts (−7*c*)	Per cent lysis (Y)	$\frac{Y}{1-Y}$
1	1·0	—	1·0	1·0	10,749	8,657	77	3·35

* Initial dilution of serum 1 : 480. † Not centrifuged, total number of counts. ‡ Supernatant from sonated cells, value for 100 per cent lysis.

Antiserum titrations were carried out in the presence of four 50 per cent units of complement. The complement titrations were carried out using optimally sensitized cells[3]. In this particular system, it was found that complement had from twenty-five to thirty 50 per cent cytolytic units per ml. All the components of this system were checked for anti-complementary activity in the sheep cell hæmolytic system and were not found to be anticomplementary in the concentrations used.

Protective Effect of orally administered S,β-Aminoethylisothiuronium.Br.HBr against X-radiation Death in Mice

S,β-Aminoethylisothiuronium.Br.HBr (AET) is of known value in mice, and given parenterally in an appropriate dose will convert a $LD_{100/30}$ dose of whole-body X-radiation to essentially a $LD_{0/30}$ (ref. 1). The oral administration of AET prior to X-radiation is said to be effective (ref. 2 and Doherty, D. G., personal communication), but no definite results have yet been published. Oral cysteamine has been reported to be effective in both mice and rats with a longer duration of action than intraperitoneal injection[3], but this has been disputed[4].

The outstanding advantage of the oral use of any chemical is, of course, ease of administration. The purpose of this communication is to present data on the oral administration of AET to mice, its toxicity, its value and its duration of action.

Young adult female mice, Walter Reed–Bagg strain, weighing 22–26 gm. were used in this work. The AET used was dissolved in a phosphate buffer of *p*H 7·2. The *p*H was then adjusted to 7–7·5 by the addition of the necessary amount of concentrated sodium hydroxide. The final concentration of AET was always about 100 mgm./c.c. based on the weight of the di-bromide salt. All solutions were prepared just before using.

Experimental animals were given 1,500 mgm./kgm. AET by gastric catheter (volume about 0·3 c.c.) while controls were given the same amount of the buffer solution alone.

At various times after AET administration exposure to 770 r. of whole-body X-radiation was carried out. Each exposure group consisted of experimental and control animals, totalling 20–30 mice. After exposure each group was housed in the same large cage, with standard laboratory food and water always available. Mortality and body-weight of the survivors were determined daily for 30 days.

The source of X-ray was a 250 Maxitron, operating at 250 kVp., 30 m.amp. Inherent filtration was equal to 3·2 mm. beryllium and half-value layer of 1·0 mm. aluminium and 1·0 mm. copper was added. The dose was measured in air in the appropriate mid-position of the animals with a Victoreen chamber. The rate of X-radiation was about 30 r./min. and the target source distance was 70 cm.

Toxicity analysis revealed that doses of AET of 1,200 mgm./kgm. or less were non-lethal to these mice. At 1,500 mgm./kgm. there was a 20 per cent mortality in the next 24 hr. Such a result was also noted in the treated X-radiated animals ; however, all such deaths were discarded from the experimental groups reported. At doses of 1,800 mgm./kgm. or greater there was 100 per cent mortality in 48 hr.

Fig. 1 presents the results of this experiment. A total of seven groups of control mice showed a remarkably similar 30-day mortality. For purposes of statistical comparison the control groups were averaged together.

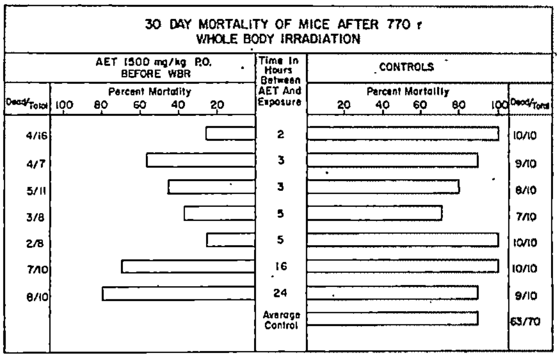

Fig. 1

AET by mouth exerts a significant protective effect at 2, 3 and 5 hr. after ingestion, but this is lost at 16 and 24 hr. Chi-square analysis of the 2 hr., 3 hr. (combined) and 5 hr. (combined) gives a $P > 0·001$ when compared with the control $LD_{90/30}$ in a total of 70 mice. The protection achieved is not so dramatic as when AET is given parenterally.

The loss of body-weight following X-radiation was similar in all groups for the first week. Thereafter, the controls continued to lose weight and eventually died, while the AET-treated mice began to regain weight and by 30 days had generally exceeded their pre-X-radiation body-weight.

AET is as effective at 5 hr. as at 2 hr. after ingestion. Duration of the protective action is unknown, but it is not apparent at 16 hr. Nor is the earliest time for protection following oral administration known from this experiment, except that it exerts its effect at least within 2 hr. Other reports indicate that protective action is apparent within a few minutes of ingestion for AET[3] and cysteamine[4].

PHYSIOLOGY

Repetitive Hyperpolarizing Response of the Nerve Fibre of Crayfish

The electrical properties of the myelinated nerve fibre in potassium-rich solution were observed by Stämpfli[1], Mueller[2] and Tasaki[3]. Those of the unmyelinated nerve fibre were observed by Segal[4], Tasaki[3] and Moore[5]. When the membrane potential is depolarized by potassium, the potential difference across the membrane produced by the inward current pulse is larger than that produced by the outward one and exhibits a kind of discontinuous increase at a certain current intensity (the current-potential relation is non-linear). The time-course of the potential difference produced by the inward current has two steps. This phenomenon is called 'anodal threshold phenomenon' by Segal[4] and 'hyperpolarizing response' by Tasaki[3]. Tasaki reported that the hyperpolarizing response in the giant axon of the squid was slightly different from that in the myelinated nerve fibre.

In the present work similar experiments were made on the single motor axon (fast closer) in the claw of the crayfish (*Procambarus clarkii*), which was smaller than the giant axon of squid and was 30–50μ in diameter. Our results accorded approximately with those obtained in the nerve fibre of other animals. Responses obtained in the crayfish giant axon sometimes resembled the hyperpolarizing response obtained in the node of Ranvier of the myelinated nerve fibre and sometimes resembled that in the squid giant axon. Besides, they often appeared in the form of repetitive responses which were not observed in the other animals.

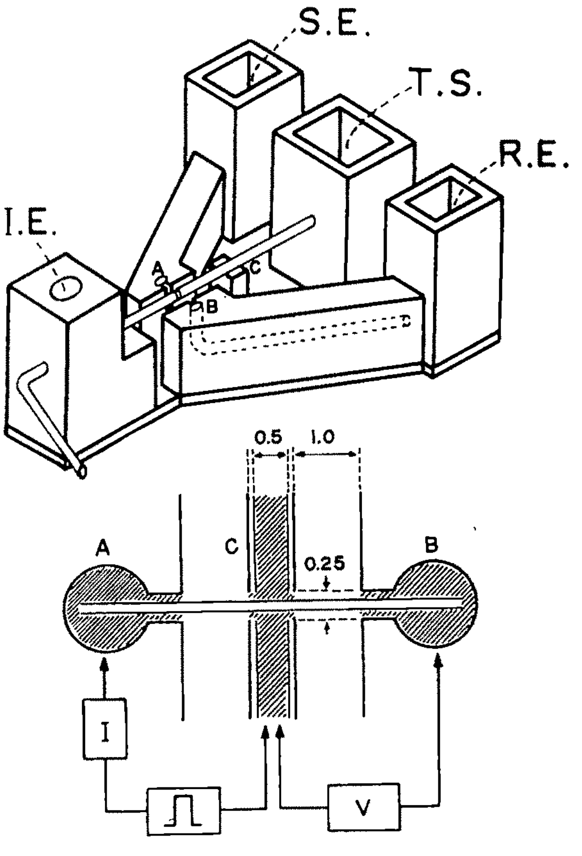

Fig. 1. Arrangement used for recording the membrane potential variation in the crayfish unmyelinated nerve fibre. The portions of the axon in pools *A* and *B* were narcotized with 0·2 per cent cocaine solution. Each pool was insulated with mineral oil

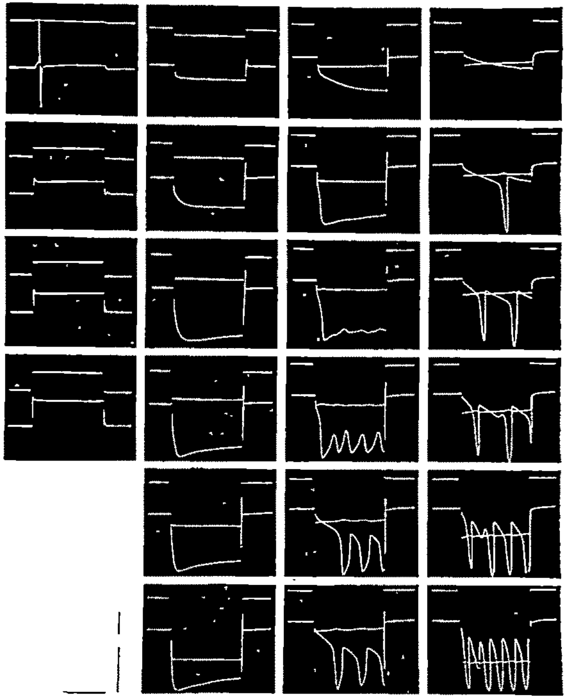

Fig. 2. Simultaneous recording of the membrane current (upper trace) and the membrane potential (lower trace) in a crayfish nerve fibre treated with potassium chloride. The concentration of potassium was increased in the order from left to right. The calibrating bar for current (upper) is 10^{-7} amp., for voltage (lower) is 50 mV. and for time is 30 msec.

A single nerve fibre was mounted in the chamber with three pools as shown in Fig. 1. The stimulators were connected with *A*-pool and *C*-pool and the potential difference between *C*-pool and *B*-pool was recorded. *C*-pool was irrigated with the test solution. The amount of potassium ions in the medium was altered by mixing isotonic potassium chloride solution with van Harreveld solution. Sodium was replaced with potassium, while chloride, calcium and magnesium were kept normal. The portions of the axon in *A*-pool and *B*-pool were narcotized with a 0·2 per cent cocaine solution. Each pool was insulated with mineral oil.

Fig. 2 shows the potential which was produced across the membrane depolarized by potassium when a square current pulse of 50 msec. was applied. In Fig. 2, the upper trace of each photograph shows the applied current and the lower trace shows the potential produced. The concentration of sodium ion was decreased and that of potassium was increased in the order from left to right. The repetitive hyperpolarizing response was observed in the potassium-rich media (the third and fourth columns of Fig. 2). Such response could be produced no matter whether the solution contained a small quantity of sodium or not. The response resembled the ordinary action potential in several respects and had the all-or-none character with a clear threshold, displaying a critical hyperpolarization. As the concentration of potassium was increased, this response became sharper and larger. The amplitude and the duration of the response in isotonic potassium chloride solution were about 80 mV. and about 5 msec. respectively. As the stimulus current was increased, the latency became shorter. The frequency of the repetitive response became higher on increasing the inward current. The repetitive response could last for more than 10 sec., and, when it ceased, the membrane potential reached the potential level lower than the peak of the response by about 20 mV.

The membrane in the potassium-rich media shows the same voltage-current characteristics as the semiconductor. The repetitive response may be produced by a negative resistance property of the membrane as known from semiconductor theory. In other words, the factor which causes the repetitive response may be explained by the spontaneous change between the two stable states of the potassium permeability, one of which is the increased state and the other of which is the decreased state[1,3,4,5].

Transmission of Swelling Characteristics by Mitochondria of Regenerating Liver

As an outcome of previous work on the fine structural changes of cell particles during induced hepatic carcinogenesis[1-3] and rapid liver growth[3], it has been found that the mitochondria isolated from regenerating rat liver transmit their swelling characteristics to the hepatic mitochondria of the host rats following intraperitoneal injection.

Male Sprague–Dawley rats (average 280 gm.), fed 'Purina chow', were used. The animals were killed 12 hr. after partial hepatectomy, where two-thirds of the liver was removed under light ether anæsthesia. The mitochondrial fractions isolated as described[2] from two animals were pooled, suspended in 3 ml. 0·25 *M* sucrose, and injected intraperitoneally to rats. The controls were injected with mitochondria from intact, non-hepatectomized rats. For the preparation of the mitochondrial membrane (crista) and intra-cristal protein fractions, the mitochondria from two partially hepatectomized rats were pooled, and suspended in 5·5 ml. of distilled water that contained, per litre, 1 ml. of a phosphate buffer (411 gm. dipotassium hydrogen phosphate + 163 gm. potassium dihydrogen phosphate per litre). The suspension was incubated for 40 min., then centrifuged for 12 min. at 25,000*g*. The sedimented membrane fraction was resuspended in 3 ml. of 0·9 per cent sodium chloride solution, while a concentrated sodium chloride solution was added to the decanted supernatant to bring the final concentration of sodium chloride to 0·9 per cent. Both fractions were injected intraperitoneally to separate animals. The swelling of the liver mitochondria of the injected animals was measured at the time-intervals shown in Fig. 1, by the optical density method as described previously[2]. All experiments were carried out in triplicate.

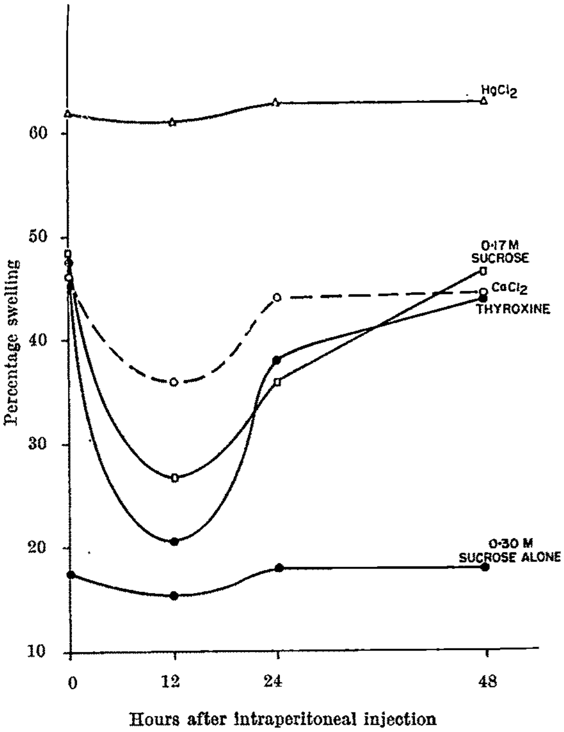

Fig. 1. Effect of intraperitoneally injected liver mitochondria obtained from partially hepatectomized rats on the hepatic mitochondrial swelling of the host rats. The test systems for mitochondrial swelling were 1×10^{-5} *M* thyroxine or mercuric chloride, or 5×10^{-3} *M* calcium chloride in 0·30 *M*, *p*H 7·4 sucrose, or 0·17 *M*, *p*H 7·4 sucrose alone. Each point on the curves corresponds to the swelling at 40 min.

In contrast to the results shown in Fig. 1, the mitochondria isolated from the control rats, which were injected with liver mitochondria from intact, non-hepatectomized animals, exhibited no, or only very slight, change in swelling. In the experiments with the isolated membrane and intra-cristal protein fractions corresponding alterations in mitochondrial swelling were observed in the thyroxine and calcium chloride test systems when the rats were injected with the membrane fraction. However, unlike whole mitochondria, injection of this fraction did not produce changes in the swelling induced by 0·17 *M* sucrose. The intra-cristal protein fraction did not produce noticeable changes in swelling with either of the test systems used.

That rapid tissue growth is associated with low levels of mitochondrial swelling has been shown previously with rat hepatoma[2-4], and with rat liver following partial hepatectomy or intraperitoneal injection of 20-methylcholanthrene[3]. In view of these results, the transmissible decrease of mitochondrial swelling, produced by mitochondria of regenerating liver, found by us correlates with the stimulation of hepatic mitotic rate by injected whole homogenates of rapidly growing tissues[5,6] or isolated microsomes and mitochondria from rapidly dividing cells[7]. Since tissue growth is associated with enhanced rate of protein synthesis which is in turn dependent on the rate of production of adenosine triphosphate, it is not unexpected that growth affects the mitochondrial membrane site of intense oxidative phosphorylation and thus, the characteristics of swelling. Hence, further evidence is provided in support of the correlation between rapid tissue growth and low values of mitochondrial swelling[2,3]. A more detailed study of the reported phenomenon is in progress.

Incorporation of Ethanol-I-^{14}C into Fatty Acids in the Normal and Alloxan Diabetic Rat

Recent work in this laboratory has shown that, in the mouse, ethanol-1-^{14}C is incorporated *in vivo* into phospholipids, cholesterol, and fatty acids at approximately the same rate and to the same degree as acetate-1-^{14}C (ref. 1). It is well known that in diabetic animals a metabolic block exists in the synthesis of fatty acids from acetate[2]. It was of interest to determine whether ethanol can be used to any greater degree as a source of building blocks for fatty acid synthesis in diabetic animals, or whether a similar metabolic block occurs.

Long-Evans rats of 250–350 gm. maintained on Wayne laboratory chow were used. Alloxan diabetes in rats was produced by the subcutaneous injection of 150 mgm. alloxan per kgm. in citric acid buffer according to Klebanoff and Greenbaum[3]. Rats were considered diabetic when urine sugar was greater than 250 mgm. per cent two weeks after injection of alloxan. Acetate-1-^{14}C and ethanol-1-^{14}C were obtained from Nuclear-Chicago. Solutions of radioactive acetate and ethanol were measured by means of a Packard Tri-Carb scintillation counter.

The incubation medium consisted of 2 or 4 μc. of ethanol-1-^{14}C or acetate-1-^{14}C diluted with 170 μM of the non-radioactive compound in 4 ml. 0·1 M phosphate buffer, *p*H 7·4. Approximately 500 mgm. of liver slices cut by means of a Stadie-Riggs tissue slicer were inserted into 25-ml. Erlenmeyer flasks containing the incubation medium, the flasks were gassed with pure oxygen and incubated for 2 hr. at 37°. At the end of the incubation time the medium was decanted on filter paper and the total lipids in the slices were isolated by the method of Baruch and Chaikoff[4]. The chloroform solutions of lipids were plated on copper planchets and the radioactivity was determined in a Nuclear-Chicago gas-flow counter using the end window.

In agreement with my *in vivo* work in mice, rat liver slices incorporate ethanol and acetate into liver lipids at approximately equal rates and to the same degree (Table 1). In diabetic animals ethanol and acetate incorporation was severely and equally depressed. In the diabetic rats, the rate of ethanol incorporation into liver lipids was 22 per cent of normal, while acetate incorporation was 17 per cent of normal. This small difference in incorporation is not considered significant. The fact that the liver slices from the diabetic animal were able to utilize ethanol and acetate to approximately the same extent in their slow rate of lipid synthesis indicates that the diabetic animal is able to convert ethanol to acetate at an adequate rate and that the metabolic block must occur beyond this point. Recent work elsewhere[5] has suggested that ethanol and acetate do not participate equally in fat metabolism. We infer from these experiments, however, that ethanol and acetate are equivalent as a source of liver lipid synthesis both *in vivo* and *in vitro*.

Table 1. INCORPORATION OF ETHANOL-1-^{14}C AND SODIUM ACETATE-1-^{14}C INTO LIVER LIPIDS IN NORMAL AND DIABETIC RATS

	Ethanol-1-^{14}C c.p.m./gm. liver slice	Acetate-1-^{14}C c.p.m./gm. liver slice
Normal (average of 12 animals)	1,111 ± 90	1,033 ± 14
Alloxan diabetic (average of 6 animals)	251 ± 49	176 ± 61

The incubation flasks contained 170 μM (2 μc.) of the radioactive compound in 4 ml. 0·1 M phosphate buffer *p*H 7·5. Incubation time was 2 hr.

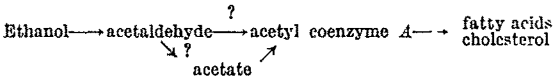
When normal liver slices are presented with either ethanol or acetate as a source of lipid building blocks, acetate is the preferred substrate. Isotopic competition studies show that equimolar amounts of non-radioactive acetate inhibited the incorporation of radioactive ethanol into lipids 75 per cent (Table 2). On the other hand, non-radioactive ethanol did not depress entrance of acetate-1-^{14}C into the lipid-building metabolic sequence more than about 10 per cent. Table 2 also shows that in alloxan diabetic animals a parallel relationship exists.

Table 2. INCORPORATION OF ETHANOL-1-^{14}C AND SODIUM ACETATE-1-^{14}C INTO LIVER LIPIDS ALONE AND IN THE PRESENCE OF EQUIMOLAR AMOUNTS OF NON-RADIOACTIVE ACETATE AND ETHANOL RESPECTIVELY

	Ethanol-1-^{14}C c.p.m./gm. liver slices	Ethanol-1-^{14}C + acetate c.p.m./gm. liver slices	Acetate-1-^{14}C c.p.m./gm. liver slices	Acetate-1-^{14}C + ethanol c.p.m./gm. liver slices
Normal (average of 3 animals)	2,294 ± 480	710 ± 142	1,947 ± 318	1.752 ± 216
Alloxan diabetic (average of 3 animals)	378 ± 16	80 ± 25	227 ± 106	201 ± 21

Conditions are as described for Table 1 except that the medium contained 4 μc. of the radioactive compound and the incubation time was 3 hr.

Whether ethanol and its oxidation product, acetaldehyde, enter the acetate pool as acetate *per se* or directly as an activated 2-carbon fragment has not yet been definitely settled. These alternatives are expressed in the following metabolic sequence :



The enzyme aldehyde dehydrogenase, which probably oxidizes the bulk of the acetaldehyde, yields acetate as the product[6]. My results suggest that ethanol follows the metabolic sequence : acetaldehyde → acetate → activated acetate, since ethanol incorporation into lipids is depressed by additional acetate, while non-radioactive ethanol dilutes the radioactive acetate incorporation not more than 10 per cent. If acetaldehyde were directly converted to acetyl coenzyme *A*, a reciprocal dilution effect between the two radioactive precursors should be observed. It is not likely that the presence of acetate is inhibiting the oxidation of acetaldehyde since this reaction is known to be irreversible. Furthermore, I have shown that acetate does not slow the rate of ethanol oxidation[7]. My results best fit the theory that acetaldehyde from ethanol is converted to free acetate before entering the metabolic pool.

Effect of Splenectomy on the Resistance of Rats to Histamine Stress

The spleen has been suggested by many investigators as a site of production of hormones or hormone-like substances; interrelationships have been postulated with the pituitary, adrenal, gonad and thyroid glands. The present communication on the relationship of histamine tolerance to splenectomy provides additional evidence for a splenic humoral contribution.

Two hundred and ten female Wistar rats averaging 75 gm. were matched by weight and divided into three groups (*A*, *B* and *C*) representing respectively splenectomized rats, sham-operated animals and normal controls. The splenectomies were completed under open-ether anæsthesia, as described by Farris and Griffith[1]. The splenic pedicle was ligated and cut as close to the hilus as possible. The incisions were closed in two layers, surgical gut being used for the abdominal wall, and silk for the skin surfaces. Sham-operated females were subjected to the same operative procedures except for the surgical removal of the spleen. After four weeks, 60 animals in each group were selected and equal numbers tested for histamine resistance. The histamine challenge was at four dose-levels, 450, 600, 750, 900 mgm./kgm. of body-weight. Identical procedures were utilized for male animals. Finney's method of probit analysis was used to calculate the LD_{50} values and dose-response lines[2].

Table 1 presents the results. Comparisons between the LD_{50} values for groups *A* and *B* indicate that splenectomy induced 5·1 per cent increase in the tolerance of female and 14·9 per cent increase in the tolerance of male rats to histamine stress. In the males, the increase approached statistical significance ($P = 0·13$). In no instance did any of the differences between the sham and unoperated controls attain or approach statistical significance. It is of interest that the increase in tolerance observed in the male was greater than the comparable increase in female rats. This finding suggests the possible existence of a sex difference in splenic function, a suggestion supported by previous reports of sex differences in response to histamine in parathyroidectomized[3] and thymectomized[4] animals.

Table 1. Effects of Splenectomy on the LD_{50} Values of Male and Female Rats

	Group *A*: splenectomized rats	Group *B*: sham-operated rats	Group *C*: normal control rats
I. *Male*			
LD_{50} (mgm./kgm. ± *S.E.*)	754·3 ± 68·2	656·6 ± 63·4	686·6 ± 56·7
Percentage difference between LD_{50} values	*A* : *B* + 14·9 per cent *A* : *C* + 9·9 per cent	*B* : *C* − 4·4 per cent	
P values	*A* : *B*, 0·13 *A* : *C*, 0·30	*B* : *C*, 0·64	
II. *Female*			
LD_{50} (mgm./kgm. ± *S.E.*)	703·8 ± 49·9	669·6 ± 54·1	661·1 ± 55·7
Percentage difference between LD_{50} values	*A* : *B* + 5·1 per cent *A* : *C* + 6·5 per cent	*B* : *C* + 1·3 per cent	
P values	*A* : *B*, 0·48 *A* : *C*, 0·38	*B* : *C*, 0·88	

A : *B*, results of comparisons between results for group *A* and group *B*, *A* : *C*, group *A* and group *C*, and *B* : *C*, group *B* and group *C*, respectively.

That splenectomy tends to increase tolerance to histamine stress is in accord with the protective action against epinephrine-induced pulmonary œdema[5] and toxic doses of 2-thio-5-methyl-uracil[6] induced by splenectomy.

Although the investigation does not offer conclusive evidence concerning a splenic endocrine function, the results provide inferential support for such a hypothesis.

An Effect of Chlorpromazine on Rat Mitochondrial Membranes

The phenothiazines used in therapy appear to affect membranes in many biological systems. Thus, Greig *et al.*[1], among others, have shown that promethazine, a phenothiazine type of antihistaminic drug, prevents the usual deterioration of red blood cells during storage. This presumably is a membrane effect. The frog gastrocnemius muscle swells when placed in distilled water. This water imbibition can be partially prevented by chlorpromazine[2]. A few *in vivo* experiments may be cited as well. Thus, the metrazol-enhanced passage of dyes into the brain is antagonized by chlorpromazine[3] ; the absorption of sugar from the intestine[4] and drugs from subcutaneous depots[5] are both retarded by chlorpromazine. Close inspection of the entire literature dealing with the actions of chlorpromazine on all types of biological systems revealed that most of the test systems employed contained semipermeable membranes of one type or another (cellular or sub-cellular). For this reason the possibility should be considered that these structures are the primary loci of attack by the drug, while the numerous other reported effects may be secondary.

Prominent among the membranes thought to be affected by chlorpromazine are those of the mitochondrion[6–8]. Roizin *et al.*[8] have presented preliminary evidence that pretreatment of rats with this drug caused changes in the size and structure of brain mitochondria. Bernsohn *et al.*[9] believed that the inhibitory effect of chlorpromazine on the enzyme hexokinase present in rat brain homogenate was an indirect one, since they were unable to demonstrate inhibition of a purified yeast hexokinase with this drug. However, no experiments with the non-particulate mammalian enzyme were performed. Although it is true that in a few isolated instances chlorpromazine does inhibit non-particulate enzyme preparations directly, this does not negate the possibility that the pharmacologically important action of this drug is concerned with changes in biological membranes. Finally, it must be considered that chlorpromazine membrane effects, such as slowing or preventing substrate uptake, or changing enzyme leakage from mitochondria, for example, could mistakenly be interpreted as an inhibition of a particular enzyme under observation.

Since a majority of the papers scrutinized employed either isolated mitochondria or tissue preparations containing mitochondria, an investigation of the effect of chlorpromazine on the permeability of these organelles to water or water-soluble ions was undertaken. It is known that the optical density of a suspension of mitochondria in an aqueous medium is a function of their volume[10]. Swelling results in a lowering of optical density which can easily be followed spectrophotometrically at the arbitrary wave-length of 520 mμ. Such swelling can be induced in both brain and liver mitochondria from Wistar rats by a variety of means, including osmotic dilution, phosphate ions plus osmotic dilution, thyroxin and many detergents, including 'Triton *X*-100'. The effect of chlorpromazine on these different types of mitochondrial swelling is shown in Table 1. Under the conditions of these experiments, chlorpromazine considerably inhibits all the types of swelling, many at low concentrations. Occasionally, effects were noted at concentrations as low as 10^{-6} *M* for brain using 'Triton' as a swelling agent, or 10^{-7} *M* for liver with thyroxin as the swelling agent. The concentrations of chlorpromazine are smaller than those generally necessary to produce changes in enzyme activities or in the level of oxidative phosphorylation.

Table 1. INHIBITION OF MITOCHONDRIAL SWELLING BY CHLORPROMAZINE

Mitochondrial source	No. of exp.	Swelling agent	Molar concentration of chlorpromazine inhibiting mitochondrial swelling 30 per cent
Brain	6	Phosphate + water	5×10^{-4}
	15	'Triton *X*-100' + sucrose	10^{-5}
Liver	6	Water	2×10^{-4}
	6	Phosphate + water	5×10^{-5}
	20	Thyroxin + sucrose	$1–2 \times 10^{-6}$
	6	None	5×10^{-6}*

* Prevention of endogenous swelling when mitochondria were suspended in 0·3 *M* sucrose.

Mitochondria from 50–100 mgm. of rat brain or 12–20 mgm. of rat liver suspended in 0·1–0·2 ml. of 0·25 *M* sucrose were added to 0·25–0·30 *M* sucrose, or water or 0·25 *M* phosphate buffer at *p*H 7·4. Thyroxin when added to liver mitochondria was present at a final concentration of 10^{-5} *M* ; 0·44 ml. of a solution of 0·125 per cent (v/v) 'Triton *X*-100' was usually added to brain mitochondria when needed. The final volume in all cuvettes was 3·0 ml. Mitochondrial swelling caused a fall in optical density which was measured by means of a Beckman Model *DU* spectrophotometer at 520 mμ. The change in optical density was generally followed over a 10-min. period.

These experiments therefore give some support for the idea that chlorpromazine primarily causes a change in membrane permeability.

Effects of Chlorpromazine and Lysergic Acid Diethylamide on the Rate of Habituation of the Arousal Response

THE responsiveness of an animal to sensory stimulation is dependent to a large extent on past experience as well as the precise conditions to which the animal is subjected. A continually repeated auditory stimulus presented in a stable environment gradually produces indifference whereas the association of a reward or a punishment brings about heightened attentiveness and increases the arousal value of the auditory stimulus[1]. Systemic administration of certain drugs may produce similar effects but for a wider range of stimuli. Blocking of sensory-induced electrocortical arousal and behavioural indifference characterize some of the central effects of chlorpromazine in cats[2]. On the other hand, *d*-lysergic acid diethylamide (LSD 25), administered in small doses, produces increased responsiveness to most sensory stimuli[3]. Chlorpromazine has also been shown to block conditioned avoidance behaviour and markedly decrease the ability of the animal to learn simple positive conditioned responses[4].

It may be that the effect of chlorpromazine on arousal responses and conditioned avoidance behaviour is due not to an all-or-nothing blocking of the responses but to an increased rate of negative learning or habituation. Conversely, LSD 25 may interfere selectively with this latter process, thereby inducing increased responsiveness. The effects of these two drugs have therefore been compared on the rate of habituation of an arousal response evoked by an auditory stimulus, both in terms of the behaviour of the animal and the electrical activity of the cerebral cortex.

Experiments were carried out on five chronic cat preparations carrying permanently implanted cortical recording electrodes. For recording purposes the animals were housed in a double-walled, semi-sound-proofed cubicle fitted with a one-way observation window. Thus the behaviour of the animal could be correlated concomitantly with the electrocortical activity. An auditory stimulus of 1,000 c./sec., obtained from an audio-oscillator, was fed into a loudspeaker fitted in a side wall of the box.

The rate of habituation of the arousal response was found to be dependent on a number of factors such as the intensity, the duration and the rate of presentation of the stimulus. Thus the experimental procedure was standardized and the auditory stimulus was presented at intervals of 5–10 min., depending on whether or not the required depth of sleep was indicated in the electrocorticogram. The duration of the stimulus was kept constant at 8 sec., while the animal was always allowed a period of acclimatization in the cubicle before each experiment was started. Each animal was habituated to the auditory stimulus at a known intensity following an injection of normal saline. When habituation was complete a very loud, brief noise was suddenly presented in an attempt to dishabituate the animal. A period of 2–3 weeks then elapsed before the same procedure was repeated after the injection of the appropriate drug. The experiments were conducted therefore in a control, drug, control sequence in order that some assessment of the amount of retention of habituation from experiment to experiment could be made. The results obtained are illustrated graphically in Fig. 1 where the number of trials required to produce habituation of the electrocortical arousal response has been plotted against the intensity of the 1,000 c./sec. tone, expressed in decibels above an arbitrarily chosen reference-level (0·1 mV. into a 15-ohm impedance).

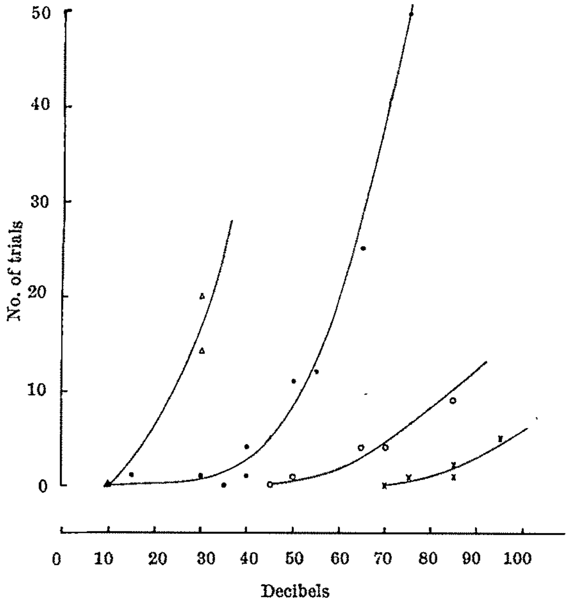

Fig. 1. Effect of chlorpromazine and *d*-lysergic acid diethylamide on the rate of habituation of the electrocortical arousal response evoked by a 1,000 c./sec. pure tone at different levels of intensity. △, 15 μgm./kgm. LSD 25 ; ●, control ; ○, 5 mgm./kgm. chlorpromazine ; ×, 10 mgm./kgm. chlorpromazine. Both drugs injected intraperitoneally

The pattern of habituation of the electrocortical arousal response was similar to that reported by Sharpless and Jasper[6]. Continued presentation of the auditory stimulus at a constant intensity brought about a progressive decrease in the period of electrocortical desynchronization until the electrical pattern of low-amplitude fast activity characteristic of the wakeful state, failed to appear. Behavioural arousal, which was indicated in the initial trials by ear movements, opening of the eyes and usually some head or body movements, or in the later stages by slight eye movements only, disappeared three to four trials before habituation of the electrocortical response.

The intraperitoneal injection of 5 mgm./kgm. or 10 mgm./kgm. of chlorpromazine was followed by an increase in the intensity of stimulation necessary to elicit the arousal response. There was also a marked increase in the rate of habituation. Where previously 45–50 presentations of the auditory stimulus had been required to produce habituation of the electrocortical arousal response, 3–4 or, with the higher dose of the drug, 1–2 trials were now sufficient to produce a similar effect using the same intensity of stimulation (Fig. 1 at 70 db.). Moreover, the period of desynchronization in the electrical record evoked by the tone before habituation took place was much shorter than in the control experiments. Behavioural arousal became habituated even more rapidly than the electrocortical response and when present in the initial trials was not very marked, being indicated by slight ear and eye movements or occasionally, at the higher intensities of stimulation, by the lifting of the head.

In contrast, following the administration of LSD 25 in doses of 10–15 μgm./kgm., intraperitoneally, the animals became increasingly responsive to all modalities of stimulation, so much so that periods of sleep activity in the electrocorticogram were very difficult to obtain. Presentation of the auditory stimulus was followed by abrupt arousal and long-lasting periods of alerting, both electrocortically and behaviourally. Thus, due either to the lack of the appropriate level of sleep activity in the electrical record or to the failure of the response to become habituated during the period when the drug was acting, it was possible to assess with some degree of accuracy the rate of habituation in only two out of a total of ten experiments with this drug (Fig. 1). These experiments demonstrated that even at low intensities of stimulation a greater number of trials was necessary before habituation occurred, indicating that the injection of LSD 25 produced a decrease in the rate of habituation.

In conclusion, it would appear that the changes in responsiveness of animals to sensory stimulation following systemic administration of LSD 25 or chlorpromazine could be brought about by the ability of these drugs to interfere selectively and antipodally with processes concerned in habituation or negative learning. The fact that there is also an increase in the intensity of auditory stimulation necessary to evoke an arousal response following chlorpromazine suggests that the effect of this drug on sensory-induced arousal is not produced solely by the increased rate of negative learning. There appears to be a decrease in the significance or meaning attached to the novel tone by the animal after this drug is injected.

Biological Activity of Some Humic Fractions isolated by means of Partition Chromatography

Humus has often been said to possess effects on plant growth over and above the value to plants of the plant nutrients it may release during growth.

Attempts have been made by Forsyth[1] and by Trojanowski[2] to extract humus and separate the constituents. Forsyth separated the aqueous extract of humus (fulvic acids), and Trojanowski isolated, by means of chromatography, the compounds of a group of hymatomelanic acids (ulmic acids), which have so far been little investigated. Hymatomelanic acids have now been isolated from various peats and composts using Trojanowski's method.

The crude material was freed from bituminous matter with a mixture of benzene and ethanol. Calcium and iron ions were removed by 0·2 *N* hydrochloric acid. The material was then extracted with ethanol, and the hymatomelanic acids precipitated from the ethanol extract by calcium acetate at *p*H 6·8. The precipitate was washed with 0·5 *N* hydrochloric acid and water, and then dissolved in acetone, the insoluble residue being removed by centrifuging. The acetone solution was transferred to a column of Whatman cellulose powder (30 gm. cellulose in a tube of diameter 3·5 cm.), saturated with acetone/water (20 : 1 vol.), and developed with *n*-butanol saturated with water + acetone (1 + 1 vol.). Under ultra-violet light five fluorescent bands were detected. The bands were eluted successively with acetone and water, and the eluates re-chromatographed on Whatman paper No. 1 in order to check their homogeneity. The paper chromatogram was developed with water/saturated *n*-butanol/acetone/ 0·5 *N* hydrochloric acid (12 : 12 : 1·5 vol.). The R_F values of the spots were 0·53, 0·73, 0·95 (for fractions from low peat), and 0·45, 0·48, 0·53, 0·69, 0·95 (for fractions from compost).

The activity of the fractions was determined by the *Avena* split coleoptile test of Thimann and Schneider[3]. Controls used were : (1) re-distilled water + sodium chloride in the same quantity as used for the preparation of the solutions of hymatomelanic acid fractions, (2) indole-3-acetic acid solution (0·0025 gm./1,000 ml.), (3) solutions prepared from the ash of hymatomelanic acid fractions.

A stimulating influence on growth was found in hymatomelanic acid fractions from low peat with R_F value 0·53 and 0·95 (concentrations of 0·01 gm./100 ml.) and in fractions obtained from compost with R_F values 0·45 (concentration 0·01 gm./100 ml.), R_F 0·53 (concentrations 0·03 gm./100 ml.) and R_F 0·95 (concentration 0·09 gm./100 ml.). The stimulating influence of these fractions is similar qualitatively to that of indole-3-acetic acid. No free indole compounds were found in the fractions examined. Under these conditions unpurified complexes of hymatomelanic acids did not show any physiological activity. The observed effects could not have been caused by the mineral constituents of the humic preparations.

A possible explanation for the findings seems to be that curvatures of this type are due to inherent differences in the response to humic substances of adjacent layers of tissue.

HÆMATOLOGY

Age and Molecular Weight of Dextrans, their Coating Effects, and their Interaction with Serum Albumin

Dextrans coat blood platelets and red cells[1] and interact with human serum albumin[2]. Recently two new problems have presented themselves. The first is that the interaction of the same sample of dextran with serum albumin appeared to be less after the dextran had been stored at 4° C. for about four years. and that the interaction of 'Synkol' (a Russian dextran of unknown age) was still less. The second is that, while the coating effects of dextrans of varying molecular weight scarcely varies, the interaction of the higher molecular weight dextrans with serum albumin has not been measured.

Effect of age of dextran on coating. Through the kindness of Dr. Norman Wheeler of the Abbott Co., we have been able to obtain two specimens of a dextran with a molecular weight similar to that of 285*W*3*A* of the Commercial Solvents Co. These two samples of dextran, made by the same process, had been stored for 6 and 40 months respectively, and will be referred to as 'new' and 'old' Abbott dextran. Their viscosity relative to that of saline buffered at *p*H 8 and their coating effect on human platelets and red cells are compared in Table 1 with that produced by 'old' dextran 285*W*3*A*. The viscosities of the new and the old Abbott dextrans are virtually identical, and are about 0·97 times that of old dextran 285*W*3*A*. The coating effects of the new and the old Abbott dextrans, determined in a vertical electrophoresis cell and expressed as U/U_0 (see ref. 1), are virtually identical, and almost the same as those of 285*W*3*A*. The coating effects do not seem to depend

Table 1

	η/η_1	Platelets U/U_0 (per cent)	Red cells U/U_0 (per cent)
Abbott new	1·22	1·31 ± 2·7	1·09 ± 1·9
Abbott old	1·23	1·32 ± 3·1	1·09 ± 1·7
285*W*3*A*	1·27	1·30 ± 2·4	1·09 ± 1·5

Table 2

	Mol. wt. × 10^{-3} (mean)	K_1	K_2	K_3	K_4	$-A$	$+D$	α_1	α_2	α_3	α_4
Abbott 'new'	86	44	42	45	42	4	4	0·0018	0·0013	0·0014	0·0017
Abbott 'old'	89	44	42	46	42	4	5	0·0018	0·0013	0·0014	0·0017
C.S.C. No. 6	194	59	26	34	50	8	8	0·0018	0·0008	0·0011	0·0015
C.S.C. No. 7	225	59	32	40	52	7	8	0·0018	0·0010	0·0012	0·0016
C.S.C. No. 8	412	59	33	41	51	8	8	0·0018	0·0010	0·0012	0·0016

on the time during which these dextrans have been stored, at least up to 40 months.

Effect of age of dextran on interaction with serum albumin. The interaction with serum albumin of new and old Abbott dextrans was compared by the micro-Tiselius method already described[2]. The highest concentration of serum albumin (Cohn's Fraction V, kindly supplied to us by the American Red Cross) was 2 per cent, and the highest concentration of dextran 1·5 per cent; the *p*H of the systems was 8·55, using Michaelis buffer. (The interaction of dextran 285*W*3*A* with serum albumin is the same between *p*H 6·6 and 9·6 in Michaelis buffered systems, and is the same at *p*H 8·6 in Michaelis and Dole buffered systems.)

The first two rows of Table 2 show the results obtained for new and old Abbott dextrans. Here K_1, K_2, K_3 and K_4 are the constants (slopes) of the four straight lines, passing through the origin, for albumin, dextran, dextran in the serum albumin–dextran mixture, and albumin in the serum albumin–dextran mixture, while α_1, α_2, α_3 and α_4 are the specific refractive increments for the same four lines. The interaction of these two Abbott dextrans with human serum albumin are substantially the same, although one had been stored for 6 months and the other for 40 months. The values $-A$ and $+D$ may indicate the extent of transfer of albumin to dextran when interaction produces a new species, but, except for saying that the formation of the new species always results in a transfer of albumin to dextran, it is not safe to be more definite.

Effect of molecular weight on interaction with serum albumin. Experiments on coating of human platelets and red cells have not shown any dependence on the molecular weight of Commercial Solvents Co. dextrans of mol. wt. 77,100–412,000 [1]. Samples of these dextrans, referred to as Nos. 6, 7 and 8, have been kept for 4 years at 4° C. in the solid state; they can each be made up as a 6 per cent solution in 1 per cent sodium chloride, dialysed against large volumes of Michaelis buffer at *p*H 8·55, and allowed to interact with 2 per cent serum albumin. This interaction is measured as already described[2].

The results are shown in rows 3, 4 and 5 of Table 2, K_1, etc., α_1, etc., and $-A$ and $+D$ having the same meaning as described for rows 1 and 2. The values suggest that there is a more extensive interaction when the molecular weight of the dextran is high, but the computations are difficult in the best of circumstances, and their reliability is lessened by the solutions of the higher dextrans being slightly opalescent; this makes the spikes slightly fuzzy, and reduces the accuracy with which the areas under them can be measured.

The coating of human red cells and platelets thus seems to be the same for dextrans of molecular weight 86,000–412,000. Low molecular weight dextrans (mol. wt. 86,000) interact to the same extent with human serum albumin whether they have been stored for 6 months or 40 months. Dextrans of high molecular weight appear to interact with human serum albumin to a greater extent than do those of low molecular weight, but the differences are small, and may be due to technical difficulties.

PATHOLOGY

Leukæmogenesis by Urethan in New-born Swiss Mice

AFTER earlier evidence that urethan induces or enhances the formation of pulmonary adenomas in rodents[1,2], more recent reports suggest a multipotential carcinogenic activity of this chemical. Salaman and Roe[3] and Graffi *et al.*[4] first demonstrated that urethan initiates skin carcinogenesis although it does not induce skin tumours when administered alone. Tannenbaum and Silverstone[5], by long-term application of urethan to the skin of inbred mice, observed not only lung adenomas but also tumours of the mammary gland, interscapular fat, and lacrimal glands. Kawamoto *et al.*[6] reported the augmenting influence of urethan on leukæmogenesis induced in low-leukæmic strains of mice by X-rays, œstrogenic hormone or methylcholanthrene. Berenblum and Trainin[7] showed that urethan treatment following X-irradiation results in a striking increase of leukæmogenesis in *C57BL* mice.

So far as the induction of leukæmia is concerned, the enhancing property of urethan is considered by these investigators as a 'co-leukæmogenic' effect, since it is generally accepted that urethan by itself is not leukæmogenic. The influence of urethan on leukæmogenesis, however, has not yet been studied in new-born mice, although there is good evidence that new-born animals are particularly susceptible to viral or chemical leukæmogenic agents[8,9].

In the present work new-born Swiss mice, less than 24 hr. old, were injected subcutaneously with a single dose of 0·05 ml. of a 4 per cent solution of urethan in distilled water. The Swiss mice were originally obtained from the Arsal Co., Rome. The incidence of spontaneous leukæmia in these animals, as controlled on several hundreds of old mice bred at random in this laboratory, is less than 1 per cent.

The results of the present experiment, which refer to a 6-months period of observation, were as follows: thirteen out of the 60 male and female mice given urethan at birth (an incidence of 21·6 per cent), developed malignant lymphomas between 73 and 157 days of age. The average age for onset of the disease was 107 days. All the animals showed striking enlargement of the thymus, which filled almost completely the chest cavity. In eight mice there was also marked involvement of superficial and deep lymph nodes as well as spleen. In addition, multiple lung adenomas were observed in all cases. Histologically, the lymphomatous lesions were of the lymphoblastic–lymphocytic type. Infiltrations of heart, lungs, liver, kidneys, gonads and bone marrow were found microscopically. In the peripheral blood there was in some cases a remarkable lymphocytosis with many immature cells of the lymphoid series, although the total number of leukocytes did not show abnormalities. In a single case, however, the leukocyte count at the final stage of the disease was about 300,000 per mm.^{3}.

From the results reported here, it would appear that urethan, *per se*, has the property of inducing leukæmia when a single dose is injected into new-born animals. The occurrence of leukæmia following the administration of an agent, such as urethan, which has been considered hitherto free from leukæmogenic activity, is probably to be regarded as dependent on factors inherent to the particular stage of development of the animals at birth[9,10].

Influence of a Liver Fraction on the Phagocytic Activity of the Reticulo-Endothelial System in Mice

The bacterial pyrogens (lipopolysaccharides) are reported to have a marked influence on the resistance of experimental animals to bacterial challenge[1]. The reaction follows a particular pattern : during the first few hours after injection there is a drop in the resistance to infection, followed by an increase which can be quite considerable. Halpern *et al.*[2] have shown that the injection of lipopolysaccharides in mice is followed by increased phagocytic activity of the reticulo-endothelial system. On the other hand, when increased phagocytic activity is achieved by some other procedure, namely, immunization with *BCG*, the lethal effect of bacterial endotoxins is greatly enhanced[3]. The explanation for this may be found in the fact that a stimulated reticulo-endothelial system will have a greater ability to phagocytize the endotoxins without the concordant ability to neutralize their toxic effect on the organism. After finding that a particular leucocytosis-promoting liver fraction had the properties of stimulating the resistance against bacterial challenge in mice, as well as in human beings, we found it of great interest to investigate whether this fraction would have some influence on the phagocytic activity in mice.

Table 1.- Effect of Liver Fractions on the Phagocytic Activity of the Reticulo-endothelial System

	No. of animals	Phagocytic index *K*	*W*/*WLS* *	Corrected phagocytic index
Experiment *A* :		Liver fraction I	0·2 mgm./mouse	6 hr. before testing
Treated	5	0·025	16·9	4·9
Controls	5	0·025	16·35	4·7
Experiment *B* :		Liver fraction I	0·2 mgm./mouse	24 hr. before testing
Treated	5	0·030	14·1	4·3
Controls	5	0·020	14·8	4·0
Experiment *C* :		Liver fraction I	0·4 mgm./mouse	24 hr. before testing
Treated	5	0·027	14·1	4·2
Controls	5	0·020	14·8	4·0
Experiment *D* :		Liver fraction I	0·4 mgm./mouse	48 hr. before testing
Treated	5	0·021	13·7	3·7
Controls	3	0·027	15·3	4·5
Experiment *E* :		Liver fraction II	0·4 mgm./mouse	24 hr. before testing
Treated	5	0·022	13·0	4·5
Controls	3	0·026	13·7	4·0

All animals tested with 16 mgm. carbon/100 gm. mice intravenously.
All liver fractions were given intraperitoneally.
* Ratio, body-weight to weight of liver and spleen.

Table 2. Effect of Liver Fractions (L.F.) on the Experimental Infection by *Salmonella Danysz* in Mice

Infection *	Substance	Dose intraperitoneal route	Time of challenge (hr.)	Mean survival time (days)
1,000 germs of *Salmonella Danysz* (intravenously)	Control	—	6	4·4
	L.F. I	0·20 ml./20 gm.	6	5·0
700,000 germs of *Salmonella Danysz* (intraperitoneally)	Control	—	6	3·55
	L.F. I	0·20 ml./20 gm.	6	4·1
	L.F. I	2 × 0·20 ml./20 gm.	first injection, after 6 hr. ; second injection, after 48 hr.	4·1

* 10 mice/group.

The liver fractions used are designated fractions I and II and were administered in doses of 0·2 mgm. dry substance per animal. The substance was dissolved in twice-distilled, pyrogen-free water and injected intraperitoneally. The control mice received saline injections. The phagocytic function of the reticulo-endothelial system was measured by the kinetics of blood clearance of 16 mgm./100 gm. mice of colloidal carbon (C11/1431*a*) according to the method described previously (ref. 3 and unpublished work by Dedichen, J., Laland, P., and Laland S.). The test was carried out 6, 24 and 48 hr. after the administration of the liver fraction. The results are shown in Tables 1 and 2. Stimulation of phagocytic activity could not be established by the method used.

Abnormalities in the Fine Structure of the Neuromuscular Junction in Patients with Myasthenia Gravis

In a recent communication, Bickerstaff *et al.*[1] were unable to demonstrate differences between the synaptic regions of myasthenic and non-myasthenic patients when muscle biopsies were examined by electron microscopy.

Although a detailed study of the fine structure changes in several biopsied cases of myasthenia gravis is being prepared for future publication, we would like to report at this time that definite alterations in both the presynaptic and postsynaptic regions of the neuromuscular junctions do occur in patients with myasthenia gravis.

Muscle biopsies were obtained from intercostal muscles and peripheral muscles of myasthenic patients without recourse to methylene blue staining or electrical stimulation and recording. Normal human endplates for examination were obtained from children and adults subjected to thoracotomy for repair of congenital or acquired cardiac defects.

Pieces of muscle obtained at the time of primary muscle incision were placed in buffered (pH 7·35) 4 per cent formol-sucrose fixative[2] for 15–20 min., washed and then put buffered (pH 7·35) into 1 per cent osmium tetroxide for 15 min. The blocks of muscle were rapidly dehydrated in graded ethanol and embedded in mixtures of 30 per cent methyl methacrylate and 70 per cent butyl methacrylate or 'Epon 812' (Shell Chemicals, New York). Thick sections were examined by phase microscopy and the blocks were trimmed to contain selected endplate areas. Silver sections were studied in an RCA *EMU 3D* electron microscope.

Two kinds of abnormalities were observed in the myasthenic neuromuscular junctions : (*a*) focal areas of decreased electron density in the normally electron-dense portion of the sarcolemmal membrane within the secondary synaptic clefts ; (*b*) extensive disorganization of endplate structure characterized by shrunken axon filaments, decreased numbers of secondary synaptic clefts, widening and clubbing of secondary synaptic clefts, and decreased numbers of mitochondria in the sole plate area.

Figs. 1 and 2 illustrate the appearance of a normal human neuromuscular junction. The axon terminal filament (*A*) and overlying Schwann cell (*S*) are separated by the primary synaptic cleft (*PSC*) from the elaborately infolded sarcolemma which forms the secondary synaptic clefts (*SSC*). A mitochondrion in the axon filament is present at *M*. Fig. 2 shows a drawing illustrating the relationships of these structures and the finely granular 'basement membrane' (*BM*) within the synaptic clefts. Figs. 3 and 4 illustrate disorganization of the secondary synaptic clefts and the moth-eaten appearance of the sarcolemma in the secondary synaptic clefts of a myasthenic neuromuscular junction. Figs. 5 and 6 illustrate at greater magnification the clubbing of the secondary synaptic clefts and the focal loss of material in the sarcolemma within the clefts.

In many of the endplates examined, abnormalities in the layered 'basement membrane' within the synaptic clefts were observed. Fig. 3 shows a single layer of 'basement membrane' in most areas whereas Fig. 5 shows loss of layered 'basement membrane' in most areas.

Pore-like defects in the axolemma described by Bickerstaff *et al.*[1] were seen in normal neuromuscular junctions as reported by others[3].

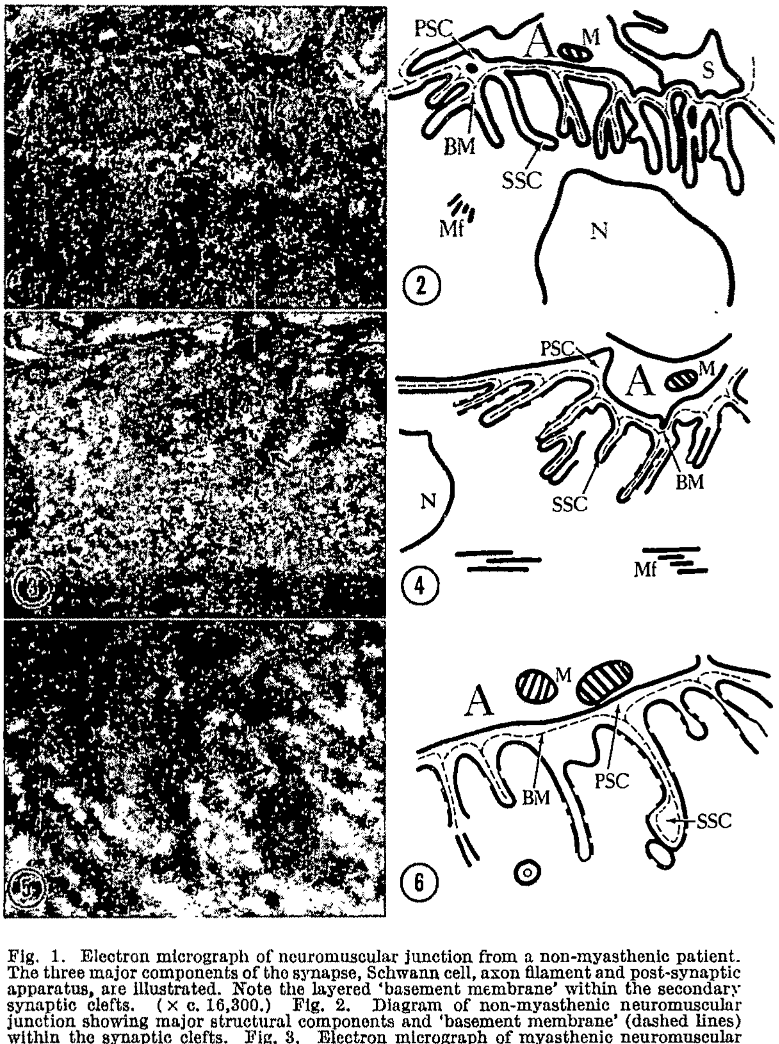

Fig. 1. Electron micrograph of neuromuscular junction from a non-myasthenic patient. The three major components of the synapse, Schwann cell, axon filament and post-synaptic apparatus, are illustrated. Note the layered 'basement membrane' within the secondary synaptic clefts. (× c. 16,300.) Fig. 2. Diagram of non-myasthenic neuromuscular junction showing major structural components and 'basement membrane' (dashed lines) within the synaptic clefts. Fig. 3. Electron micrograph of myasthenic neuromuscular junction showing disorganization of the synaptic clefts and focal areas of thinning and disruption of the sarcolemma within the secondary synaptic clefts (marked with arrow). (× *c.* 16,000). Fig. 4. Diagram of myasthenic neuromuscular junction prepared from Fig. 3 showing the changes illustrated in Fig. 3. Fig. 5. Electron micrograph of myasthenic neuromuscular junction showing swelling and clubbing of secondary synaptic clefts, moth-eaten appearance of the sarcolemma within the secondary clefts and loss of layering of the 'basement membrane' within the secondary clefts. (× *c.* 24,000.) Fig. 6. Diagram of myasthenic neuromuscular junction prepared from Fig. 5 showing the changes illustrated in Fig. 5

A, Axon filament ; *BM*, 'basement membrane' ; *M*, mitochondria ; *Mf*, muscle filaments ; *N*, nucleus ; *PSC*, primary synaptic cleft ; *S*, Schwann cell ; *SSC*, secondary synaptic cleft

Although it is premature to attempt to correlate the abnormalities observed in the fine structure of myasthenic neuromuscular junctions with the physiological abnormality in these patients, our investigations indicate that definite morphological alterations occur which may be related to the functional disability.

We wish to thank Dr. Kermit Osserman for making these biopsies available for examination.

BIOLOGY

Variation in the Secondary Sex-Ratio of the Grey Seal *Halichoerus grypus* (Fab.) during the Breeding Season

Hewer[1] has suggested that the secondary sex-ratio (that is, the sex-ratio at birth) of the grey seal is probably close to equality. Since this publication, considerably more data have been collected on the grey seal colony on the Farne Islands, Northumberland, by members of the Natural History Society of Northumberland, Durham and Newcastle upon Tyne. Of 1,433 calves which were tagged, sexed and aged between 1952 and 1959 inclusive, 731 were males and the remaining 702 females; a result which does not differ significantly from a 1 : 1 sex-ratio and which confirms Hewer's findings.

Despite the very nearly equal sex-ratio obtained, distinct differences were found when the sex-ratio was examined in relation to the time of the breeding season. Coulson and Hickling[2] have shown that there is little annual variation in the breeding season of the Farne Island colony of grey seals, and it is therefore reasonable to group data collected over a number of years into the same fortnightly periods. As is shown in Table 1, there is a distinct tendency for the sex-ratio to change from a preponderance of males at the beginning of the breeding season (in late October) to a markedly higher proportion of females at the end of the breeding season ($\chi^2 = 8\cdot56$, 3 d.f., $P < 0\cdot05 > 0\cdot01$). This result could be produced by the male calves being born, on average, earlier than the female calves. This, in fact, does occur but the difference is small, the average difference being less than 3 days.

Table 1. Sex-Ratio of Grey Seal Calves on the Farne Islands according to their Date of Birth

Year	Date of birth							
	Oct. 14–27		Oct. 28–Nov. 10		Nov. 11–24		After Nov. 24	
	♂	♀	♂	♀	♂	♀	♂	♀
1952	8	4	16	18	12	8	8	8
1953	12	8	11	16	5	10	3	8
1955	5	8	43	42	20	25	9	14
1956	7	6	43	47	47	47	24	32
1957	36	22	114	96	67	60	13	18
1958	1	1	57	38	45	38	11	10
1959	2	2	69	61	34	41	9	14
Total	71	51	353	318	230	229	77	104
Sex-ratio	100 : 71·8		100 : 90·1		100 : 99·6		100 : 135·1	

While seasonal differences in the sex-ratio of domestic and laboratory mammals have been recorded by Parkes[3], this type of difference in the sex-ratio has not been recorded before in the Phocidae.

Dissociation of Isohæmagglutinin Formation and Tolerance of Skin Grafts in Chicks

The administration of homologous whole blood into the embryo or new-born animal can produce either tolerance of skin grafts[1] or lead to the suppression of the isohæmagglutinin formation[2]. The causal relationship between these two types of immunological areactivity, however, remains obscure. It could be due to the fact that an identical antigenic stimulus is needed for agglutinin formation and transplantation immunity. There is evidence that red blood cells and some other tissue cells have some antigens in common. After the transplantation of tumours in mice and rats[3] and after the transplantation of skin in mice, rabbits and chicks[4], agglutinin formation was revealed even in those instances where the participation of red blood cells transferred in the graft could be ruled out. On the other hand, at least in mammals, red blood cells alone were not able to produce immunity against skin grafts[5].

In the present experiment, we investigated the formation of isohæmagglutinins in 13 chicks tolerating skin grafts after previous immunization with blood of the donor of the graft. Tolerance was produced in six individuals by mutual application of the skin graft immediately after hatching, in seven individuals by a similar skin transplantation with simultaneous administration of 0·5 ml. of heparinized blood of the donor. At the age of 6–12 weeks the tolerant chicks with the feathered graft, which had taken, were immunized with six 1-ml. doses of fresh citrated blood of the donor, administered intravenously. Plasma specimens for estimating the agglutinin titres were withdrawn in three-day intervals for two weeks after immunization was started.

In 10 from a total of 13 chicks tolerating the skin graft on the sixth to tenth day after the beginning of immunization, the formation of isohæmagglutinins against red blood cells of the donor of the graft and blood was detected (Table 1). The antibody response was relatively uniform, the maximum titres being 1/8–1/16. The grafts remained even after immunization in most chicks tolerating the graft for at least six weeks without any signs of destruction. Only in two animals they disintegrated between the fourth and sixth week after immunization. The immune response following the immunization by blood of the donor thus did not influence the fate of the tolerated homografts. Agglutinins developed in all animals where the tolerance was produced by the graft alone.

Table 1

Tolerance induced on the first day after hatching by :	No. of animals	Maximal titres of agglutinins after immunization	No. of animals with feathered grafts more than 6 weeks after immunization
Skin grafting	6	16, 16, 16, 16, 8, 8	4
Skin grafting and whole blood	7	16, 16, 8, 8, 0, 0, 0	7

Two grafts were destroyed between the fourth and sixth weeks after immunization. Three tolerant animals did not produce agglutinins even after repeated immunization.

but only in 4 out of 7 chicks where the tolerance was produced not only by the graft but also by the administration of blood on the first day after hatching. The remaining three tolerant animals did not develop any agglutinins, even after repeated immunization. Serological evidence was provided that the erythrocytes of the donors differed as to their antigens from those of their tolerant partners. These three animals not only tolerated grafts but also the red blood cells which were administered to them immediately after hatching.

From the results it appears that the cells of the skin graft alone are not capable of producing tolerance for red blood cell antigens. This is the reciprocal picture of the former finding that erythrocytes alone, administered during the adaptive period, are unable to produce tolerance of the skin graft in chicks[6]. If we can assume that this dissociation is caused by the antigen difference of red blood cells and tissue cells, then it can be also concluded from our results that some erythrocyte antigens are absent in tissue cells.

It cannot be ruled out, however, that the dissociation of both types of tolerance could be caused by factors other than antigen differences between erythrocytes and the cells of the skin graft. It is, for example, possible that the transplantation alone on the first day after hatching produces in the chicks some type of a local immunological tolerance. Finally, the temporarily tolerated skin graft could survive further also on grounds other than the persistence of the state of specific immunological activity of the recipient.

Inhibition of the Development of a Marine Sessile Community

BETWEEN October 1958 and September 1959 two panels of 'Tuffnol', each 2 ft. square, were suspended on either side of a raft at Port Royal, Jamaica. The purpose of these panels was to collect data on the settlement of an ascidian, *Ascidia nigra*. Each panel was examined at 2-monthly intervals, the two panels being examined on alternate months. When a panel had been examined it was cleaned before replacement on the raft. In this way a fresh settlement surface was provided each month. In the course of the two months in which a panel was exposed a dense growth of sessile animals always developed on it, usually dominated by *Balanus amphitrite* and *Didemnum maculosum*, with smaller numbers of other ascidians (*A. nigra*, *Diplosoma macdonaldi*, *Symplegma viride*, *Polyclinum constellatum*), serpulid worms, lamellibranchs, bryozoans and the alga *Enteromorpha sp.*

On October 1, 1959, it was necessary to find an alternative place to hang the panels, and they were moved to another raft close which already had hanging from it six panels that had been in the water continuously for 26 months. These latter panels were dominated by a community of sponges of several species, sea anemones (*Aiptasia tagetes*) and ophiurans (*Ophiothrix angulata*) with an associated fauna of crustaceans, polychæte worms, and molluscs. There were very few ascidians in these communities.

The panel which was raised and examined on November 1, 1959, had a fairly normal community on it ; but it should be noted that this would have developed from larvæ settling before the panels were shifted. The panel examined on December 1 had been in the new position for the whole of the 2 months of exposure, and had a completely different appearance from anything hitherto seen. Considerable portions of the panel had not been colonized at all, and elsewhere there were only small numbers of barnacles and serpulids, a few sponge colonies, a few colonies of the ascidian *Botryllus planus* and 16 specimens of *A. nigra*. On January 4, when the other panel was again examined after 2-months exposure at the new site, the effect was more marked. Barnacles and serpulids were almost entirely absent from this panel, there were no *A. nigra*, only one small colony of *D. maculosum*, and along one margin of the panel there were several oysters (*Isognomon alatus*). Otherwise small thin sponge colonies and a few filaments of algæ were the only noticeable colonisers.

The reduction in colonization was not due to a reduction in available larvæ or to any physical change in the environment such as temperature or salinity changes in the water. This is amply demonstrated by the fact that on a similar raft, moored 20 ft. from this one, normal colonization occurred. This other raft had eight clean panels attached to it on October 1, and by December 1 they were all covered by a *Balanus-Didemnum* community with all the usual associated animals. Only four of these panels were on the same level in the water as the test panels on the other raft : these had an average of 28 *A. nigra* on each.

Four of the above eight panels were removed on December 1 and replaced by clean panels. By January 4 the latter had developed a normal *Balanus-Didemnum* community, and the two panels on the level of the test panels had 48 and 51 *A. nigra* respectively. Observations could not be continued into 1960.

It is clear from the foregoing observations that development of a normal sessile community was inhibited on the two panels inserted in among the mature sponge-anemone-ophiuran community, and it is also clear that this was a purely local effect not observed 20 ft. away. In every respect other than a small difference in panel size and the presence of the sponge community the two environments seemed identical. Each raft was the same size and in the same depth of water and the arrangement of the panels on them was the same in each case. The inhibition was not due to any ageing effect of the panels as the same panels developed normal communities at a later stage when removed from the sponge community. The only possible explanation is that the mature sponge-anemone-ophiuran community actively inhibited the development of a primary community on the clean panels. It is not possible at present to say what form this inhibition takes: it could either prevent larval settlement or prevent survival and growth of young sessile stages. The absence of large barnacle settlements suggests the former possibility as dead shells would probably persist if metamorphosis had occurred. Nor is it possible to say what is its cause, but it is probably an attribute of the sponges rather than other members of the mature community. The high filtration-rate of a sponge community could deplete the surrounding water of food for the young primary colonizers, or the secretion of mucus or chemical toxin might kill the young stages.

Acknowledgement is made to the Nuffield Foundation for receipt of a research grant at the time these observations were made.

The Deepest Recorded Fishes

THE number of fishes from the hadal zone (in depths between about 6,000 and 11,000 m. in the deep-sea trenches) is very limited. The *Princesse-Alice* collected *Bassogigas profundissimus* (Roule) at 6,035 m. in the east Atlantic Ocean[1], the *Galathea* collected a species of Liparidae (Kermadec Trench, 6,660–6,770 m.) and *Bassogigas* sp. (the Sunda Trench, 7,160 m.)[2], and the *Vitjaz* collected *Careproctus* (*Pseudoliparis*) *amblystomopsis* Andriashev and another species of that genus from the Kurile-Kamtchatka Trench (7,210–7,230 m.) and from the Japan Trench (6,156 and 7,587 m.)[3–5]. Thus, the last-named depth is the hitherto greatest known depth from which any fish has been brought up.

During the truly remarkable dive of the U.S. Navy bathyscaphe, the *Trieste*, in the Mariana Trench in January 1960, the vessel remained on the bottom for 20 min. at a (corrected) depth of 35,800 ft. (10,912 m.) The only living creatures observed by the two men on board, Engineer Jacques Piccard and Lieut. Don Walsh, were a "shrimp" and an animal which Piccard[6] described as "a true fish", being "apparently of the sole family, about a foot long and half as wide. . . . [It] moved away from us, swimming half in the bottom ooze, and disappeared . . ." (p. 235). It was "tentatively described as *Chascanopsetta lugubris*" (p. 230). Walsh[7] mentioned it as a "flat-fish" which was "white and about a foot long".

There are several reasons for considering these statements as being somewhat dubious. First, flatfishes are commonly known as a primarily littoral order with a number of bathyal, but no single truly abyssal species (Chabanaud's record[8] of *Bathysolea profundicola* (Vaillant) having been captured between 2,000 and 4,000 m. depth is erroneous, the species being known only from between 250 and 1,290 m.). The only two species which penetrate beyond 1,500 m. are *Citharichthys dinoceros* Goode and Bean (201–1,746 m.) and *Poecilopsetta beani* (Goode) (203–1,639 m.), both from the West Indies. The deepest recorded flatfish from the *Galathea* Expedition was from 750 m. depth[9], and no flatfish was collected in or close to any of the trenches investigated. *Chascanopsetta lugubris* Alcock was previously recorded only between depths of 220 and 977 m.

Secondly, it seems very probable that certain groups of the trench fauna have a distinct lower limit. Decapod crustaceans and bryozoans are certainly not able to penetrate into the hadal zone and other important marine groups such as cirripeds, asterids, echinids, tunicates, and fishes have not been recorded at depths exceeding some 7,000–7,500 m.[10]. It is true that the number of trawlings deeper than 7,500 m. is limited to (at least) 22, but the majority of these catches have constantly yielded representatives of the really significant, hadal animals, such as actinians, polychaetes, isopods, amphipods, prosobranchs, lamellibranchs, and holothurians. Negative records are naturally of less value, but should be taken into account also.

Thirdly, it seems to appear from most of the observations made from bathyscaphes that even zoologists have great difficulties in recognizing the creatures seen through the porthole. In the case in point the animal was observed "swimming half in the bottom ooze". If it was not a fish, its remarkable size would indicate that it was probably some kind of holothurian, for example perhaps related to the bathypelagic, cushion-shaped *Galatheathuria aspera* (Theel). Hansen and Madsen[11] found the gut of this extraordinary animal to be partly filled with remains of pelagic forms and with various bottom foraminiferans and sponge spicules. The animal is almost 1 ft. long and oval in outline.

A New Intermediate Host of Schistosome Trematodes from New South Wales

RECENTLY schistosome larvæ have been discovered in the snail *Siphonaria denticulata* Quoy and Gaimard. Cercariæ from infected snails cause a typical schistosome dermatitis in man.

Schistosome dermatitis occurs along parts of the coast of New South Wales. Infections usually occur in sandy estuarine lakes where the snail *Velacumantus australis* (= *Pyrazus australis*) harbours the schistosome, *Austrobilharzia terrigalensis* Johnston[1]. However, cases of schistosome dermatitis have occasionally been reported from marine rock pools where no *Velacumantus* snails occur. An examination of a number of different species of snails from such places showed that *Siphonaria denticulata* harboured schistosome cercariæ. A typical schistosome dermatitis followed exposure to these cercariæ.

An examination of 100 *Siphonaria* from part of a rock platform at Cape Banks, Sydney, showed an infection-rate of 35 per cent. At low tide this area is often crowded with the gull *Larus novae-hollandiae.*

Twenty-five budgerigars (*Melopsittacus undulatus*) were exposed to naturally emerged cercariæ, or cercariæ from crushed snails. Immature schistosome worms were recovered from the liver or lungs of five birds. The worms appear to belong to the sub-family Bilharziellinae.

It is interesting to note that the host snail, *Siphonaria,* belongs to a pulmonate family (the Siphonariidae). Members of this family bear a superficial resemblance to limpets, but may be distinguished from them by a groove which runs down inside the right-hand side of the shell. Members of the Siphonariidae are normally found in the upper littoral zone of rocky shores. Their distribution is almost world wide, but they are especially common around the shores of the Pacific and Indian Oceans[2].

Because the Siphonariidae have such a wide geographical distribution, and their normal habitat is often the resting place of birds of the seashore, one might expect them to be the hosts of larval schistosomes in many other places.

The assistance of Mr. A. J. Bearup is gratefully acknowledged.

Transmission of Gall-Diseases of Cacao, Mango, and Pigeon Pea

'CUSHION-GALL' disease of cacao is widely distributed throughout South America[1] and has been reported also from Ghana[2] and Nigeria and Ceylon[3]. The disease has been found in most old cacao plantings in British Guiana, in the 'green-point' form, and was recorded and described by A. W. Bartlett[4] as long ago as 1905, although his report was only rediscovered in 1959. The presence of the 'flowery' type has yet to be confirmed.

Hutchins[2] has transmitted the disease successfully in Costa Rica by tissue implantation, while workers in Ghana (Tinsley, T. W., personal communication, November 1959) have transmitted a similar disease using the single cotyledon technique.

In the present work the 'green-point' type gall of cacao was transmitted by using the half-bean technique: galls were produced three weeks to a month after inoculation. Washings from the surface of galls, or extracts of macerated gall tissue transmitted at a rate of 1/7. The germination-rate of half-beans treated with gall inoculum was markedly lower than that of controls treated with distilled water.

Galls similar to the 'green-point' form of cacao have been found on mango and pigeon pea. Distilled water washings, and extracts of gall tissue of these species were inoculated into cacao half-beans. Galls were visible in the axils of the cotyledons about one month after inoculation.

The transmission-rates were:

	Washings		Tissue extract	
Mango	13/35	16/25	15/35	17/25
Pigeon pea	7/25		9/25	

The galls produced by inoculation from mango material were indistinguishable from those produced by inoculations from cacao 'green-point' material. While most of the galls produced on plants inoculated with pigeon pea gall were similar to cacao-gall, in some, the axillary bud enlarged very considerably and became chlorotic, with no proliferation of other buds. The germination-rate of the treated plants was comparable with those of controls with distilled water.

Transmission of the mango gall into a two-month cacao seedling was also obtained by inoculation of the axillary bud with tissue extract.

In the absence of any knowledge of vectors of 'cushion-gall' of cacao the significance of these results is difficult to assess. However, the ease with which the diseases of mango and pigeon pea can be transmitted to cacao under laboratory conditions would suggest that the cultivation of these two species in close proximity to cacao should be avoided.

Puccinia polysora on *Tripsacum laxum* and *Zea mays*

THERE would appear to be the impression that, in the Carribbean, the same strain of *Puccinia polysora* attacks both *Tripsacum laxum* (Guatemala grass) and *Zea mays*. In Trinidad during 1953–54 an attempt to cross-inoculate uredospores from the two species proved completely unsuccessful. Successful inoculation of the same species was a matter of routine. It was not possible to detect any morphological differences between the strains, but they are certainly quite distinct. *T. laxum* is at present free from attack by *P. polysora* in Eastern Nigeria.

MICROBIOLOGY

Slime-wall Formation in the *Salmonellae*

THE formation of a 'slime wall', which is usually a property of *Salmonella paratyphi B* but not of *S. paratyphi B* var. *java,* has long been used as a criterion of differentiation between these two organisms[1–4]. According to Birch-Hirschfeld[5], the slime-wall consists of a nitrogen-free polysaccharide containing more than 40 per cent of glucose. It is formed on solid media, optimally at temperatures of about 20–25° C. and not at 37° C. In this laboratory it is regularly demonstrated by incubating platings on solid media, initially at 37° C. overnight, and afterwards at 21° C. The slime-wall is usually evident after 24 hr. at 21° C. In the search for a reliable medium on which to demonstrate its formation, it was found that the concentration of phosphate exerted a powerful influence on the production of the polysaccharide. The basic solid medium used in these experiments contained 2 per cent of 'Bacto' dehydrated nutrient broth (Difco Laboratories), 0·85 per cent sodium chloride and 1·2 per cent New Zealand powdered agar ; it is referred to hereafter as Difco agar. Sörensen buffer, *p*H 7·0, was mainly used as the phosphate source. It was added to Difco agar in concentrations of *M*/5 doubling in dilution to *M*/160 ('phosphate agar'). The favourable effect on slime-wall production was strongest at *M*/5 and diminished progressively with the fall in phosphate concentration, little effect being observed beyond *M*/20, which was adopted as the lowest phosphate concentration for routine use. In strains of *S. paratyphi B* that were slime-wall positive on Difco agar, the amount of slime produced was greatly increased in the presence of phosphate. Strains that formed slime in small amounts or irregularly on nutrient agar produced it in abundance when phosphate was added. Some cultures that were consistently negative on nutrient agar secreted slime on *M*/5, *M*/10 and *M*/20 phosphate agar, others on *M*/5 and *M*/10, and yet others on *M*/5 phosphate agar only.

I was able to classify *S. paratyphi B* by these reactions. Strains that produced slime freely on Difco agar corresponded to classical *S. paratyphi B* and did not ferment D-tartrate. Strains forming slime sparsely or not at all on Difco agar, but abundantly on the same medium reinforced with *M*/20 Sörensen buffer, were mostly isolated from cases of food poisoning, but occasionally from cases of enteric fever. These were usually D-tartrate positive. Strains that formed slime only on *M*/5 phosphate agar were D-tartrate positive and came almost entirely from cases of food poisoning, although one strain reacting in this way has caused enteric fever. The typing phages of Felix and Callow[6,7] divided these strains into groups of types characteristic of each of the three varieties described. Exceptions to these reactions, in addition to the one already quoted, were found, however ; for example, one phage type, associated only with food poisoning, was slime-wall negative and D-tartrate negative. From this stock I have isolated both slime-wall positive and D-tartrate positive clones. It has been possible in a number of other strains to isolate slime-wall negative mutants from slime-wall positive stocks, and vice versa (see ref. 2). Within slime-wall positive lines, mutants were found that varied in the amount of slime they produced. These variations were often apparent only on phosphate agar.

An exploration of organisms of every group of the Kauffmann–White scheme of *Salmonella* serotypes revealed that, while very few indeed synthesized slime on Difco agar, the great majority produced it on phosphate agar. The most abundant production of the polysaccharide was on media containing *M*/5 phosphate, and some strains produced it only on such media. Others were able to form it when the phosphate concentration was reduced to *M*/10, and yet others on *M*/20 phosphate agar. The slime wall is uniform in appearance throughout all the *Salmonellae* tested, usually taking the form of a raised marginal ring, clearly demarcated and opaque by transmitted light and rather 'silky' when viewed by oblique illumination. Obvious slime production occurs only when the *p*H is 6·5 or higher. Between *p*H 7·0 and *p*H 8·0 it is formed freely, *p*H 7·0 being used as a routine in my experiments. Below *p*H 6·5 the colonial morphology is 'rough'.

Buffers other than Sörensen's were tried at *p*H 7·0 ; but few stimulated better slime formation than unbuffered Difco agar. Sodium glycerophosphate was very active, however, and a concentration of *M*/5, adjusted to *p*H 7·0 with sodium dihydrogen phosphate or hydrochloric acid, produced colonies that were completely mucoid after 24 hr. at 21° C. The metallic ions in the phosphates were not essential for slime-wall synthesis, for glycerophosphoric acid adjusted to *p*H 7·0 with ammonium hydroxide was equally active.

The presence of a fermentable carbohydrate, in the form of 0·5 per cent glucose, increased the amount of slime formed but was not essential for its synthesis in strains that produced it freely on Difco agar. Some strains forming slime only on phosphate agar, however, required the addition of glucose for its production. (The basic Difco medium employed in these experiments contained no detectable reducing sugar.)

The slime is not formed under anaerobic conditions.

It is not yet apparent whether the phosphate operates purely as a non-toxic buffer that does not inhibit slime-wall synthesis, or whether it participates in the synthesis. Some of the other buffers tested were clearly inhibitory in the higher concentrations used.

Whether or not the polysaccharide of which the slime is formed is identical in all *Salmonellae*, it is evident that the system that synthesizes it is similar throughout. This system is now under closer examination. Work is in progress on the conditions governing slime formation, the chemical and immunological nature of the polysaccharides, and on the possible effects of phosphate on the elaboration of other antigens. The results of these investigations will be published at a later date.

Note added in proof. An exploration of other members of the Enterobacteriaceae, for example, *Escherichia coli* and *Arizona*, has shown that the phenomenon of slime-wall formation in the presence of relatively high phosphate concentrations is widely distributed in this family.

CYTOLOGY

Chromosomes of the Wild Mushroom

VERY little work has been done on the cytology of the wild mushroom *Agaricus campestris* Fr. var. *tetrasporus*. Most investigations have been confined to cultivated mushrooms (reviewed by Evans[1,2]). The cytology of the wild form is also of considerable interest since such information may contribute to our understanding of why it has not been possible to cross the wild with the cultivated form in attempts at introducing commercially desirable characters, such as an improved flavour.

Colson[3] examined both varieties of mushroom and found that the haploid chromosome number, seen as bivalents at meiosis, was 9 in both varieties. In a variety grown on a commercial scale in Great Britain, Evans[1] found a higher haploid chromosome number, $n = 12$, which he attributed to either: (*a*) different strains of the fungus having different chromosome numbers or (*b*) differences in chromosome number being due to limitations of technique. Previous observations were made on sectioned material whereas Evans's observations were made by means of a squash technique which facilitated study of entire cells.

Since the only previously recorded chromosome number of the wild mushroom was by means of a section technique, the work reported here was carried out by means of a squash technique in order to ensure that entire cells were being examined.

Fruit-bodies of the wild mushroom were collected from permanent pasture land at Aberystwyth, at the stage when the veil had just ruptured revealing part of the hymenium. Gills, at this stage, were fixed in Evans's mixture[1] of chloroform, ethanol and glacial acetic acid (7 : 5 : 2) immediately, in the field. Squash preparations were obtained with acetic orcein after sufficient hydrolysis of tissue with hydrochloric acid (to remove basophilly of the cytoplasm) for the study of meiosis in the basidium. Twelve bivalents were observed at the first division of meiosis. The clearest count obtained was at diakinesis (Fig. 1). It was more difficult to separate the bivalents after they had become orientated around the metaphase plate. Another difficulty in counting bivalents was non-synchronization of separation of chromosomes of the bivalents, at late metaphase–early anaphase.

Thus the chromosome number of both wild and cultivated mushroom varieties, as determined by a squash technique, is $n = 12$, which supports the suggestion of Evans[1] that "previous counts may have erred on the low side" due to the inadequacy of the sectioning method for chromosome counting.

It appears that the failure to hybridize the wild and cultivated varieties[4] does not simply depend on a difference in chromosome number. It is possible that an incompatibility system[5] and a difference in breeding system mechanism are involved. Thus research on the breeding mechanism, so far, indicates that the cultivated (2-spored) variety is a homothallic heterokaryon[2,6], whereas the wild variety is a heterothallic heterokaryon like most other 4-spored hymenomycetes[4].

This work was conducted at the Department of Agricultural Botany, University College of Wales, Aberystwyth, under the direction of Prof. P. T. Thomas, whose help and encouragement are gratefully acknowledged.

GENETICS

Glutamic Dehydrogenase in Single-Gene Mutants of *Neurospora* Deficient in Amination

FINCHAM[1,2] described some amination-deficient (am^-) mutants of *Neurospora crassa* which lacked the glutamic dehydrogenase and, therefore, could grow only very slowly in minimal medium in the absence of exogenous L-glutamic acid. Normal growth of the am^- mutants occurred in media containing glutamate, aspartate, alanine, ornithine or arginine, but not glycine, serine, threonine, histidine, lysine or citrulline[2]. The effectiveness of various amino-acids in supporting the growth of the am^- mutants was later correlated[3] to the efficiency of enzymatic transamination between these amino-acids and α-ketoglutarate in cell-free extracts. The growth of am^- mutants on exogenous sources of amino-acids is thus without doubt due to their conversion first to glutamic acid by transamination.

The very slow growth of the am^- mutants on minimal medium, however, has never been explained. It could perhaps be due to the formation of traces of glutamic acid by transamination between α-ketoglutarate and some other amino-acids initially synthesized by the cells. So far as we are aware, however, the only major path of entry of ammonia in *Neurospora* is the reductive amination of α-ketoglutarate. It is therefore difficult to visualize how the am^- cells produce other amino-acids in the absence of glutamic dehydrogenase. Earlier, Sanwal[4] had demonstrated the presence of two different glutamic dehydrogenases, one specific for diphosphopyridine nucleotide (DPN) and another for triphosphopyridine nucleotide (TPN) in a related fungus, *Fusarium*. In following up this work with wild-type strains of *Neurospora crassa*, Sanwal and Lata[5] succeeded in separating and purifying the TPN- and DPN-specific glutamic dehydrogenases. The glutamic dehydrogenase of *Neurospora* was reported to be specific for TPN[2] but later found[6] to be non-specific with regard to its coenzyme requirement.

The discovery of two different glutamic dehydrogenases[5] raised some interesting questions pertaining to the one-gene one-enzyme hypothesis. If single-gene *am*$^-$ mutants had lost the ability to grow in the absence of some exogenous source of L-glutamate, did it mean that one gene mutation had affected two different glutamic dehydrogenases? To test this point we used two *am*$^-$ mutants, 32213 *R*1*a* and 47305 *A* (both single-gene mutants) obtained through the courtesy of Dr. M. B. Mitchell of the California Institute of Technology, Pasadena. The wild-type strain, R^+, was kindly supplied by Dr. P. K. Issac of the Department of Botany, University of Manitoba. The strains were grown in shake cultures from a conidial inoculum[5] in the minimal medium *N* of Vogel[7] supplemented with 0·1 per cent L-glutamate and the specific activity of the DPN-specific and TPN-specific glutamic dehydrogenases was determined[5] in cell-free extracts of 24-hr. and 48-hr. mycelial growth. Table 1 summarizes the results of this investigation.

Table 1. SPECIFIC ACTIVITY OF DPN- AND TPN-SPECIFIC GLUTAMIC DEHYDROGENASES OF WILD-TYPE STRAIN R^+, *am*$^-$ *32213 R*1*a* AND *47305 A* OF *Neurospora*

Strain	Hr. of growth	DPN-enzyme	TPN-enzyme
R^+	24	90	320
	48	87	101
*32213 R*1*a*	24	32	none
	48	63	none
47305 A	24	61	none
	48	83	none

It will be seen from Table 1 that the wild-type strain produces both enzymes, but the *am*$^-$ mutants produce only the DPN-specific glutamic dehydrogenase. It is clear, therefore, that the mutation of one gene has led to the loss of only one enzyme, the TPN-specific glutamic dehydrogenase. The slow growth of the *am*$^-$ mutants on minimal medium is now understandable on the basis of the presence of the DPN-specific enzyme, but it is not easy to understand why the mutants cannot grow as well as the wild-type strain in the minimal medium. We have demonstrated[5] that the affinity of the TPN-specific enzyme for α-ketoglutarate is higher than the DPN-specific enzyme, but this fact alone is not sufficient to explain the slow growth of the mutants unless it is argued that the DPN-specific enzyme is primarily a degradative enzyme and the TPN-specific enzyme is biosynthetic[4,5]. We shall publish data elsewhere in support of this argument.

SOIL SCIENCE

Interpretation of the Upper Plastic Limit of Clays

THE upper plastic limit, or liquid limit, of clays is regarded as that water content at which sufficient free water is present to allow clay particles to slip past one another under a certain applied force. It can also be interpreted as the distance between particles or between structural units of particles at which forces of interaction between the clay particles become sufficiently weak to allow easy movement of particles or units relative to each other. This interpretation allows an easier explanation of the influence on the liquid limit of such factors as exchangeable ion, salt concentration and *p*H of the clay paste. For this interpretation it is convenient to define an 'interaction volume' for a unit mass of clay particles as that volume within which individual particles or units of particles interfere with the movement of adjacent particles or units. The interaction volume will decrease as the applied force increases.

In addition to the influence of exchangeable ions on the liquid limit, for which published results have been summarized[1], it is necessary to know the influence of electrolyte concentration since this controls interparticle forces and particle arrangement in many clay pastes. Liquid limit values were measured according to a standard soil mechanics procedure of determining the number of blows required to close a groove in the clay paste samples using the Casagrande liquid limit device. Three or four water contents were used for which the number of blows fell between 15 and 40, and the water content at the 25-blow point (the liquid limit) was read from a plot of water content versus the logarithm of the number of blows. Water content was expressed on oven-dry weight of soil corrected for the weight of salt. Values for liquid limit are influenced by the procedure and by the drying and preparation history of the sample. These factors were kept constant, and only relative values of liquid limit are discussed.

The dominant interparticle force in pastes of montmorillonite with monovalent exchangeable cations is a repulsion arising from osmotic activity of the diffuse ion-layer around the particles[2]. Fig. 1 shows the measured liquid limit of sodium montmorillonite at different concentrations of sodium chloride. An increasing salt concentration, which results in a decrease in interparticle repulsion, decreases the liquid limit. The repulsion between particles can be considered to determine the interaction volume, keeping the particles in a fixed configuration with respect to each other and preventing free movement. As the repulsion is decreased, the particles become free to move at lower water contents or lower interparticle distances, and the liquid limit decreases.

When the repulsion is decreased by substituting a divalent exchangeable ion such as calcium, the liquid limit is also decreased. However, for calcium montmorillonite, increasing salt concentration does not decrease swelling by the predicted amount, and in Fig. 1 it did not decrease the liquid limit appreciably. Repulsion between individual particles resulting in large interparticle distances is not the dominant force. The clay paste consists of units of particles separated by 9 Å. within the unit. Larger separations occur between these units[3]. This structure or particle arrangement, which changes little with increasing salt concentration, determines the interaction volume or the water content at which interaction between units is low enough to allow easy movement.

In kaolinite pastes interparticle forces also control the liquid limit through their influence on particle arrangement. The dominant influence of particle arrangement is shown in Fig. 2 by the values with distilled water. The untreated clay has a *p*H of 4 and the particles are flocculated in an edge-to-face arrangement which results in a high interaction volume[4]. The neutral clays with a *p*H of 6·5 are still flocculated but the forces of attraction are lower. Fewer edge-to-face perpendicular contacts result in a lower interaction volume. In the dispersed sodium-saturated clay at *p*H 10 the interparticle force-resisting movement is the repulsion between particles which keeps them in more parallel arrangement. This is low for the kaolinite and the effective interaction volume is small. With increasing salt concentration the structure of all samples changes to face-to-face particle arrangement[4] with lower interaction volume than the edge-to-face but higher than the parallel arrangement. If the minimum in liquid limit for the dispersed clay at 0·01 *N* sodium chloride is real, it may result from decreased repulsion due to increasing salt concentration which initially decreases interaction volume more rapidly than the flocculated particle arrangement increases it.

For other clays the variation of liquid limit with electrolyte concentration may show a different pattern depending upon the interaction volume resulting from the interparticle forces. Limited measurements with a clay from the St. Lawrence Lowlands, which contains illite and chlorite, show the liquid limit passing through a shallow maximum at intermediate salt concentrations. This could result from the formation of a flocculated structure which becomes more compact as repulsion decreases due to further increases in salt concentration.

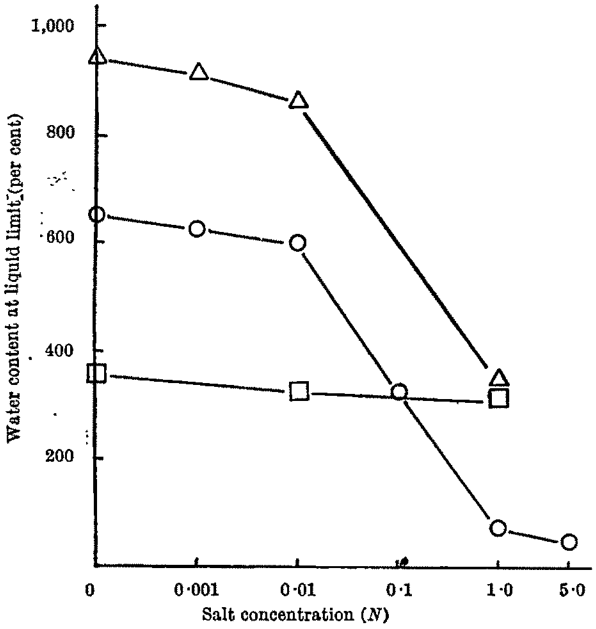

Fig. 1. Influence of salt concentration on liquid limit of montmorillonite clay with different exchangeable cations. △, sodium montmorillonite + sodium chloride; ○, natural bentonite + sodium chloride; □, calcium montmorillonite + calcium chloride

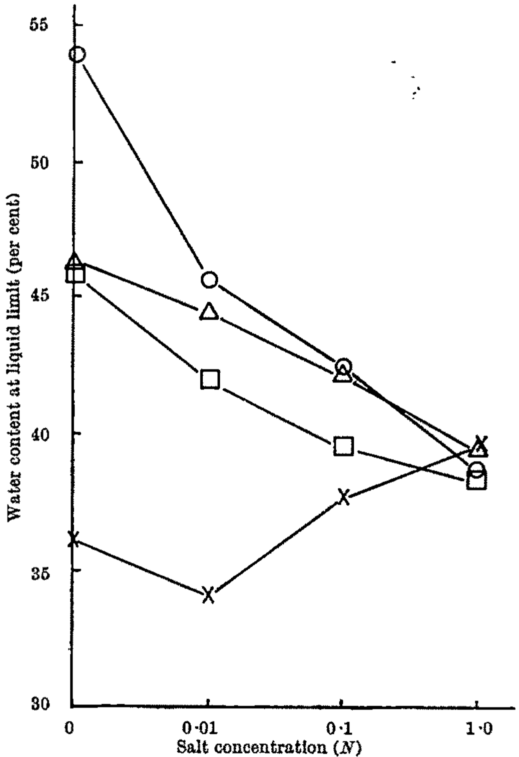

Fig. 2. Influence of salt concentration on liquid limit of kaolinite clay at different *p*H and with different exchangeable cations. ○, natural kaolinite (*p*H 4) + calcium chloride; △, sodium kaolinite (*p*H 6·5) + sodium chloride; □ calcium kaolinite (*p*H 6) + calcium chloride; ×, sodium kaolinite (*p*H 10) + sodium chloride

This interpretation of liquid limit controlled by interparticle forces explains why the liquid limit decreases with increasing valence of exchangeable ion for high-swelling clays, but increases for low-swelling clays where interaction volume is determined largely by particle arrangement. Here polyvalent ions lead to a more flocculated structure with a higher interaction volume.

At very high electrolyte concentration and in the presence of dissolving salt, clay pastes may become very stiff or show an increase in liquid limit. This effect has been termed ionotropy[5]. A definite structure or particle arrangement results from the salt diffusing into the clay paste. The intensification of *d* (001) spacings in X-ray diffraction patterns of salted clay pastes[6] indicates that the clay particles are in parallel orientation.

I wish to acknowledge the grant-in-aid of research from the National Research Council, Canada, under which this work was done, and the assistance of Mr. R. K. Chang, who made most of the measurements.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, April 17

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. P. Alexander: "Science and Epistemological Atomism".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Education of Engineers—All's Well?" opened by Sir Hamish D. MacLaren, K.B.E.

Society of Chemical Industry, Pesticides Group (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Annual General Meeting.

Institute of Metal Finishing (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. J. Edwards: "Plating of Zinc-Based Die-Castings".

Institution of Mechanical Engineers, Hydraulic Plant and Machinery Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 7 p.m.—Discussion on "Co-ordinating the Needs of Hydraulic Machinery and Civil Engineering".

Monday, April 17—Tuesday, April 18

Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals (at the Royal Commonwealth Society, Craven Street, London, W.C.2)—Discussion on "The Appraisal of Powders for Pressing and Sintering".

Tuesday, April 18

Institute of Fuel (at the Royal United Service Institution, Whitehall, London, S.W.1), at 5.30 p.m.—Prof. Hoyt C. Hottel (Massachusetts Institute of Technology: "Radiative Transfer in Combustion Systems"* (Twenty-ninth Melchett Lecture).

Wednesday, April 19

British Association for Commercial and Industrial Education (at Senate House, University of London, W.C.1), at 10.40 a.m.—Conference on "New Routes to Further Education".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Annual General Meeting and Presidential Address.

Bone and Tooth Society (at the Institute of Orthopædics, 234 Great Portland Street, London, W.1), at 5.15 p.m.—Dr. Franklin C. McLean (University of Chicago): "The Parathyroids and Vitamin D in Calcium Homeostasis".

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Dr. E. F. Drion: "The Intercorrelation between the Nutrients Consumed by a Group of Families in the Netherlands"; Mr. J. A. Heady: "Diets of Bank Clerks".

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. A. N. Arman, Dr. F. J. Miranda and Mr. G. R. Bishop: "Progress in Oil-Filled Cables and Their Accessories".

British Institution of Radio Engineers, Medical Electronics Group (at University College Medical School, University Street, Gower Street, London, W.C.1), at 6 p.m.—Dr. C. N. Smyth: "Instrumentation for Obstetrics".

Institution of Mechanical Engineers, Education and Training Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Undergraduate Project Work in Full-time and Sandwich Courses in Mechanical Engineering".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Dr. K. L. Blaxter: "The Nutritional Physiology of Livestock Under Natural Conditions" (Fernhurst Lecture).

Society of Instrument Technology, Data Processing Section (at 26 Portland Place, London, W.1), at 6.15 p.m.—Annual General Meeting. 7 p.m.—Mr. T. H. Flowers: "Electronic Telephone Exchanges".

Wednesday, April 19—Thursday, April 20

Institute of Rural Life at Home and Overseas (at the Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1), at 2.30 p.m. on Wednesday and 10.30 a.m. on Thursday—Eleventh Annual Conference on "The Land in Trust—at Home and Overseas".

Thursday, April 20

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. P. Benjamin and Mr. C. Weaver: "The Adhesion of Evaporated Metal Films on Glass"; Mr. C. J. S. Chapman, Mr. J. M. Gregory, Mr. R. W. Hill and Mr. M. W. Johns: "Nuclear Alinement of Cobalt and the Decay of Cobalt-55".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting followed by Scientific Papers.

Linnean Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. R. Melville: "Bracken Regeneration from Sporelings"; Dr. John Ramsbottom: "A Letter from the Swedish Consul announcing the Arrival of the Linnean Collections"; Prof. L. J. Audus: "Recent Studies on Geotropism".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. K. Stein: "On Holomorphic Maps in the Space of Several Complex Variables".

Institution of Electrical Engineers, Utilization Section (joint meeting with the London Graduate and Student Section, at Savoy Place, London, W.C.2), at 6 p.m.—Mr. P. J. H. Rata: "Aluminium in Electrical Engineering"; Mr. A. D. Swanston and Mr. B. W. Towell: "Diesel Railway Locomotives"; Mr. T. E. S. Rickard: "Automatic Programming for Hot Reversing Mills".

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Mr. C. H. C. Brown: "Some Laboratory Investigations in connexion with the Development of Cationic Bitumen Emulsions".

Thursday, April 20—Friday, April 21

British Kinematograph Society, and the Television Society (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2)—Convention on "Television and Film Techniques".

Thursday, April 20—Thursday, May 4

Engineering, Marine, Welding and Nuclear Energy Exhibition (at Olympia, London).*

Friday, April 21

Society of Chemical Industry, Fine Chemicals Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Annual General Meeting. 7 p.m.—Prof. F. Bergel, F.R.S.: "Newer Developments in Carcino-Chemotherapy".

Institution of Electronics (in the Large Lecture Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 7 p.m.—Mr. T. D. Towers: "Modern Transistors and Their Applications".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Mathematics—The Principal, Borough Road College, Isleworth, Middlesex (April 21).

Assistant Lecturer in Physical Chemistry—The Registrar, The University, Hull (April 26).

Assistant Lecturers (2) (one with qualifications in the field of pure mathematics and the other with qualifications in the field of applied mathematics) in the Department of Mathematics—The Registrar, The University, Manchester 13 (April 27).

Assistant Lecturer in Statistics; a Lecturer or Assistant Lecturer in Applied Mathematics; and a Lecturer in Pure Mathematics—The Registrar, The University, Sheffield (April 29).

Assistant Lecturer or Lecturer in Pure Mathematics—The Registrar, University College, Singleton Park, Swansea (April 29).

Demonstrator in the Department of Geography—The Registrar and Secretary, King's College (University of Durham), Newcastle upon Tyne 1 (April 29).

Senior Lecturer in Inorganic Chemistry (Durban); and a Lecturer in Inorganic Chemistry (Pietermaritzburg), University of Natal, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, April 30).

Assistant Chief Geologist (with an appropriate university degree (preferably with honours), together with wide geological experience in the investigation of sedimentary basins and particularly in exploration and development of oilfields) in the Bureau of Mineral Resources, Department of National Development, Commonwealth of Australia, to be responsible for the Bureau's sedimentary programme of geological investigation of the sedimentary basins of Australia; prepare advice on problems related to the search for oil; and to assist the Chief Geologist in technical and administrative matters—Official Secretary (Ref. 61/2083), Australia House, Strand, London, W.C.2 (May 1).

Assistant Director (with post-doctoral research experience, preferably in the application of the electron microscope and related physical methods in biology or medicine) of Research in the Electron Microscope Section of the Cavendish Laboratory—The Secretary of the Appointments Committee of the Faculty of Physics and Chemistry, Chemical Laboratory, The University, Lensfield Road, Cambridge (May 1).

Lecturer or Assistant Lecturer (honours graduate in zoology or physiology) in the Department of Zoology—The Registrar, The University, Leeds 2 (May 1).

Lecturer (with an honours degree in physiology or an allied subject, or equivalent training) in the Department of Physiology—The Secretary, The University, Edinburgh (May 1).

Lecturer or Assistant Lecturer in the Department of Organic Chemistry—The Registrar, The University, Leeds 2 (May 5).

Research Demonstrator (with experience or interest in stratigraphy, structure and/or stratigraphical palæontology) in the Department of Geology—The Registrar, University College of South Wales and Monmouthshire, Cardiff (May 5).

Assistant Lecturer (preferably with interests in ecology, particularly its physiological aspects) in Botany—The Registrar (Room 22, O.R.B.), The University, Reading (May 6).

Demonstrators (2) in the School of Agriculture—The Registrar and Secretary, King's College (University of Durham), Newcastle upon Tyne 1 (May 6).

Postdoctoral Fellow in the Department of Chemistry, to carry out research into the reactions of halogen atoms with organic molecules, in collaboration with Dr. J. M. Tedder—The Registrar, The University, Sheffield 10 (May 6).

BURN RESEARCH FELLOW (graduate, less than 30 years old, with two to three years research experience) IN PHARMACOLOGY at Oxford—Secretary to the Trustees, Department of Pharmacology, University of Oxford (May 15).

DEMONSTRATOR IN BOTANY—The Registrar, The University of Adelaide, Adelaide, South Australia (May 15).

READER IN PHYSIOLOGY at the Royal Free Hospital School of Medicine—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 18).

ASSISTANT LECTURERS IN APPLIED OR PURE MATHEMATICS at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, May 19).

LECTURER (with a good honours degree in zoology, and preferably some experience of teaching and research) IN ZOOLOGY at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong and London, May 30).

CHAIR OF GEOGRAPHY in the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, May 31).

LECTURER or ASSISTANT LECTURER (preferably candidate interested in genetics and ecology) IN ZOOLOGY—The Registrar, Pius XII College, Roma, Basutoland, Southern Africa (May 31).

CHAIR OF PHYSIOLOGY in Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, June 10).

ASSISTANT LECTURER IN INORGANIC CHEMISTRY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

PHYSICISTS AND CHEMISTS (with an honours degree or equivalent in physics or chemistry with at least three years relevant experience, or Associates of the Royal Institute of Chemistry) as Reactor Operating Staff at Dounreay Experimental Reactor Establishment, Thurso, Caithness, Scotland, to take control of a shift team responsible for the safe and efficient operation of the high flux Materials Testing Reactor, its ancillary plant and the experimental test rigs under irradiation in it—The Personnel Manager, D.E.R.E., U.K.A.E.A., Dounreay, Thurso, Caithness, Scotland, quoting Ref. 214/34.

PLANT PATHOLOGIST (male, aged between 28 and 45, with an honours degree in botany having specialized in mycology, together with at least two years postgraduate experience, and preferably experience in plant diseases in the tropics, especially diseases of cocoa) in Sierra Leone, to advise the Director of Agriculture on the application of phytosanitary measures and to undertake investigations into the control of plant diseases—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD/63/15/019.

RESEARCH ASSISTANTS (graduates) IN THE DEPARTMENTS OF BOTANY AND ZOOLOGY, CHEMISTRY, MATHEMATICS, METALLURGY (GEOLOGY), AND PHYSICS—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

RESEARCH ASSISTANTS (with a degree in chemistry or chemical engineering, or with equivalent qualifications such as Grad.R.I.C.) IN THE DEPARTMENT OF CHEMISTRY, for experimental work on the thermodynamic properties of gases and of liquid mixtures—The Bursar, The University, Reading.

SENIOR LECTURER (well qualified academically in mathematics, and preferably with industrial and teaching experience) IN MATHEMATICS—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 8/G.

SENIOR TECHNICIAN or TECHNICIAN IN THE CLINICAL ISOTOPE LABORATORY—The House Governor, St. Mary's Hospital, Paddington, London, W.2.

Comparison of the β-Lactoglobulins of Buffalo's Milk and Cow's Milk.—Dr. A. Sen and N. K. Sinha 343
Intracellular Distribution of Ubiquinone in Rat Liver under Certain Stress Conditions.—Dr. A. S. Aiyar and Dr. A. Sreenivasan . . 344
Extraction of Nucleic Acid-free Lipopolysaccharides from Gram-negative Bacteria.—G. J. O'Neill and Prof. J. P. Todd 344
Enzymatic Reduction of Diphosphopyridine Nucleotide with Urea.—Hirohisa Omura and Yutaka Osajima 345
A D-Lactic Dehydrogenase from *Leuconostoc mesenteroides*.—E. Kaufmann and Dr. S. Dikstein 346
Stimulation of Active Transport of Sodium from Sodium-rich Frog Muscle by Insulin and Lactate.—Roderick P. Kernan 347

PHYSIOLOGY

Urocanicacidurea associated with Hepatic Coma.—Dr. William M. McIsaac and Irvine H. Page 347
Effect of Chronic High and Low Salt Intakes on Adrenocortical Function.—Dr. Lewis K. Dahl, Lawrence Silver, Sanford Spraragen and Malcolm Smilay 348
Hypothalamic Control of Lactogenic Function in the Cat.—Hanus J. Grosz and Alan B. Rothballer 349
Release of 5-Hydroxytryptamine from Rat Mast Cells *in vitro*.—Dr. G. T. Archer 350
nteraction of Acetylcholine, Calcium and Depolarization in the Contraction of Smooth Muscle.—Dr. K. A. P. Edman and Dr. H. O. Schild 350
Influence of Changes of Blood Volume on the Concentration of Aldosterone in Peripheral Plasma of Intact Unanæsthetized Dogs.—Ejgil Bojesen and Hans Degn 352
Œstrogen Antagonisms: 19-Norprogesterone and 18,19-Dinortestosterone as Œstrone Antagonists.—Richard A. Edgren 353

RADIOBIOLOGY

Lead-210 in Some Human and Animal Tissues.—C. R. Hill and Dr. Z. S. Jaworowski . . 353
Incorporation of Phosphorus-32 into Adenosine Triphosphate of Adrenal Chromaffin Granules.—W. H. Prusoff, Dr. H. Blaschko, Dr. Margery G. Ord and Dr. L. A. Stocken . . . 354

PATHOLOGY

Production of Pyrogenic Substances by Extracts of Delayed Hypersensitive Cells mixed with Antigen *in vitro*.—Dr. J. Johanovský . . 355
Induction of Mammary Carcinoma in Hypophysectomized Rats treated with 3-Methylcholanthrene, Œstradiol-17β, Progesterone and Growth Hormone.—Dr. Stretton Young . . . 356

HÆMATOLOGY

Identity of the α-Chains of the Minor Human Hæmoglobin Components A_2 and A_2' with the α-Chains of Human Hæmoglobin A and F.—Prof. Titus H. J. Huisman, Dr. Bennett Horton and Miss Tine B. Sebens 357

CYTOLOGY

Aggregation of Protein Particles in Tumour Cells.—A. Bolognari 358
Distribution of Deoxyribonucleic Acid in the Cell Nucleus.—E. Grundmann 359
Differences in Mechanism of Staining Reaction for Mast Cells of Some Lower Vertebrates.—Dr. A. Stolk 360

BIOLOGY

Perception of Distance in Animal Echo-Location.—L. Kay; J. D. Pye; Jan Nordmark . . 361
Insecticide Resistance in Mosquitoes.—Dr. G. Davidson and Dr. C. Elizabeth Jackson . . 364
Parental Care in a Rare Spider *Pellenes nigrociliatus* (L. Koch) var. *bilunulata* Simon.—Dr. Izabella Mikulska 365
Flowering Behaviour of Vanilla.—James E. Irvine and Norman E. Delfel 366
Striate Mosaic: a New Disease of Sugar Cane.—C. G. Hughes 366
Moisture Conditions for testing Germination.—Prof. N. Collis-George and Jocelyn E. Sands . 367

ENTOMOLOGY

Termination of Diapause in *Acheta* by Urea.—T. W. Hogan 367
The Prothoracic Gland and Colour Change in Locusts.—Peggy E. Ellis and Dr. D. B. Carlisle 368
Experimental Hybridization of *Aedes* (*Stegomyia*) *aegypti* (L.) with *A.* (*S.*) *simpsoni* (Theobald).—G. A. H. McClelland 369

VIROLOGY

Use of a 'Mixed Hæmadsorption' Method in Virus-infected Tissue Cultures.—Dr. Astrid Fagraeus and Dr. Åke Espmark 370
New Herbaceous Test-Plants for Study of the Infectious Degeneration of Grape Vines.—E. Baldacci, A. Amici, P. Bonola, E. Betto, G. Fogliani and E. Refatti 371

GENETICS

Gene Action in the X-chromosome of the Mouse (*Mus musculus* L.).—Mary F. Lyon . . . 372
Genetic Basis for Graft-against-Host Immunological Reactions between Two Inbred Lines of Chickens.—L. N. Payne and P. Jaffe . . . 373

MISCELLANY

Extra-Terrestrial Radio Transmissions.—Leland I. Anderson 374

DIFCO

microbiological reagents and media

THE ONLY COMPLETE LINE

DETECTION OF THE SALMONELLA-SHIGELLA GROUP

Bacto-SS Agar

is a selective medium especially designed for use in isolation of fastidious *Shigella* and *Salmonella* strains. The selective action of this medium restrains to a large extent the development of coliform bacteria with minimum restriction of fastidious strains of the pathogens. Because of the inhibitive action of the medium of coliform bacteria, it is possible to inoculate the medium heavily with faeces thereby greatly increasing the chance of positive isolations from samples containing very few pathogens.

Bacto-Bismuth Sulphite Agar

is a highly selective medium for isolation of *Salmonella typhosa.* The unusual selective properties of this medium permit the use of large inocula of faeces and other suspected material without overgrowth of extraneous intestinal bacteria.

Bacto-MacConkey Agar

is an excellent differential medium for use in conjunction with Bacto-SS Agar and Bacto-Bismuth Sulphite Agar. This medium supports rapid and luxuriant growth of even the most fastidious strains of the typhoid-dysentery group.

Although MacConkey Agar does not inhibit coliform bacteria it does afford excellent differentiation of colonies of pathogens from those of the lactose fermenting bacilli.

Bacto-Tetrathionate Broth Base
Bacto-Selenite Broth

enrichment media for isolation of intestinal pathogens. These are excellent aids in the detection of carriers and examination of other materials for members of the *Salmonella-Shigella* group.

Please send for the latest technical information.

BTL

complete laboratory service

BAIRD & TATLOCK (LONDON) LIMITED, CHADWELL HEATH, ESSEX, ENGLAND.

Branches in London, Manchester and Glasgow.

TAS/DO.1

Ultra-Violet & Infra-Red Sampling Instruments

ULTRA-VIOLET ABSORPTION CELLS
VARIABLE path-length cells for liquids
FIXED path-length cells for liquids

KBR EVACUABLE DIE
for making 13, 15 and 16 mm. Discs

INFRA-RED ABSORPTION CELLS
VARIABLE path-length cells for liquids
FIXED path-length demountable and sealed cells for liquids
MICROCELLS for liquids
GAS cells in pyrex and metal

HYDRAULIC 30-TON PRESS
especially designed for KBr Disc Technique

Rotating Electrode (Solution Excitation) Spark Unit

HIGH-SPEED VIBRATION MILL
indispensable for KBr Disc Technique
available for 230 volt 50-cycle and 110-volt 60-cycle mains

ROCK-SALT POLISHING KIT

RIIC Sampling Instruments are marketed by the leading spectrometer manufacturers of the world. Descriptive literature on application.

A TRIUMPH FOR SCIENCE

IN *Nature* of October 12, 1957, p. 719, we were glad and proud to congratulate the scientists and technologists of the U.S.S.R. on the successful launching of the first artificial Earth satellite (*Sputnik I*). Less than a month afterwards (*Nature*, 180, 931; 1957), we again had occasion to congratulate the U.S.S.R., when the second satellite (*Sputnik II*) was launched, this time containing a dog. Though both these satellites eventually disintegrated in space, enough evidence had been obtained, especially from *Sputnik II*, to indicate that it was possible for living things (even mammals) to withstand the strain of being launched into orbit. Since then, Russian, American and other scientists have made astounding progress in space research using rockets, satellites, etc. Two more recent achievements, perhaps most important of all, were the placing into orbit of satellites containing dogs and recovering them with the dogs alive. This was done by scientists in the U.S.S.R. on August 16, 1960, and again on March 9 of this year.

The significance of these great achievements, all made so recently as during the past four years, needs no stressing now; but one cannot refrain from expressing concern that though each achievement has deservedly received world-wide acclaim, the science and technology behind each are, by and large, known only to the chosen few.

Now again, on April 12, a still further point in scientific advancement was reached, for on that day scientists and technologists in the U.S.S.R. reaped a rich reward for concentrated and ingenious research by successfully launching another space-vehicle (*Vostok*) into space. This satellite carried, among other things, a man (Major Yuri Alekseyevich Gagarin), travelled in orbit around the Earth in 89 min. 6 sec., and a little later was brought back safely to Earth, with Major Gagarin unharmed—all in about 108 min. Moreover, the Russians claim that every part of the space-vehicle was recovered intact and can be used again. (See also p. 307 of this issue.)

The entire world, scientists and non-scientists alike, has learned of this great feat with awe and admiration, and we hasten to praise and congratulate the scientists and technologists who were responsible. Moreover, Major Gagarin is to be commended on his courage and devotion to duty.

It seems timely, therefore, once again to emphasize what we consider to be the true significance of the magnificent results obtained in space research by Russian, American and, indeed, other men of science. We may ask: Are these great feats being worked for, paid heavily for and finally achieved amidst world applause mainly for political prestige or military advantage, or for the advancement of science in its truest sense, that is, the enhancement of man and his culture ? There is certainly no gainsaying the scientific results, for they are there for all to see; and the scientists and technologists concerned (most of them, apart from Kapitza, Sedov and Blagonravov, for example, unknown outside the U.S.S.R.) are, it is assumed, being awarded their just honours and dues. But the time has long since passed when the scientist either need not or does not concern himself with the consequence of his work; so the most important question now is: How are these magnificent scientific achievements to be utilized in the near and distant future ? Quite rightly, we think, the scientist himself should not be the sole arbiter in this problem. But it is for everyone to see that the right people make the right decisions for the sake of world progress and peace. We are often being told that it is the people of a nation and the peoples of the world who decide policy and make final decisions, and that their so-called leaders, especially in the political arena, are not really their leaders but actually their servants. If this is the case, then the world community must see that scientific results are used wisely; but the community can do so only if it has a true understanding and appreciation of the significance and message of science.

But it is very doubtful if the layman really appreciates what is going on in the world of science to-day, despite the greater attempts at improving education both through specialized agencies such as universities and technical colleges and through mass media. Our formal academies of teaching and learning, such as schools and universities, cannot, by themselves, prepare the ground for the most desirable growth, development, appreciation and application of the new knowledge. Neither will the plausible projects of increasing the number of universities and technical colleges solve the problem; they can only scratch the surface.

There are other means of education, equally important, albeit mainly mass education—television, sound broadcasting, the cinema, books and, above all, the newspaper Press; but, alas, all too often these soon become reduced to arenas for political propaganda.

Ignorance provides the most fertile ground for undesirable propaganda of all sorts, especially politics. So to what extent does the Press attempt to give science its fair due, and thus lay the foundation for creating the type of mind that can assess wisely the value of any form of scientific achievement, whether it be in space research or antibiotics ? It is very significant, alarmingly so, in fact, that the Press seems to have developed a poor sense of values, and preys on the weakness and foibles of human nature rather than attempts to stimulate the interest of its readers in things of greater moment and of inestimably more value to man and his cultural development. It is a sad reflexion that it takes a man travelling in orbit around the Earth to give science one of its all too few banner headlines in the newspapers. The same could be said of other aspects of cultural development which aims at international collaboration and peace. It is relevant here to refer to a recent American survey which has shown that a certain film actress was mentioned more often than anyone else in the world in the daily newspapers of 1960.

Another comparison may not come amiss. A photograph of a section of a crowd in Moscow, taken just after the *Vostok* news was released, seemed reminiscent of a photograph of a crowd outside the entrance to a London hospital. But there was a difference, in that the former wore, with understandable justification, jubilant and happy expressions on their faces, whereas the latter seemed taut, anxious and expectant, for they were a crowd of Press photographers anxious to take photographs of visitors to another film actress lying ill in the hospital. The sense of values of both Press and public on the two sides of the Iron Curtain seems to be vastly different.

Many of the comments on the recent news from the U.S.S.R., at any rate in the British Press, betrays a deplorable lack among some writers of a true appreciation of the technique, aims and objectives of science. Moreover, a sense of proportion seems to be sacrificed to sensationalism. For example, one feature article is devoted entirely to urging Britain to award some form of honour to Major Gagarin. It is fairly certain that to bestow on Major Gagarin an honorary George Cross, in recognition of his courage and bravery, would meet with popular acclaim; but, alas, the article in question directs all its proposals to British scientific societies, including a suggestion that the Royal Society of London should consider conferring the great scientific distinction of foreign membership on the Major. We have no doubt that it can be left to the Royal Society to maintain its sense of proportion, and while, perhaps, officially congratulating the Academy of Sciences of the U.S.S.R., continue to confine its distinguished foreign membership to scientists who have personally made outstanding contributions to fundamental scientific knowledge.

Another writer refers to scientists as being the "most optimistic and dangerous men in the world". Men of science can ill afford to ignore such absurd suggestions and comments about themselves, in spite of the fact that most ill-informed statements concerning science appear in the so-called 'popular' newspapers. The fact that science is so misrepresented should give cause for grave concern, for it is such newspapers which enjoy the largest circulation and are therefore read by the majority of people.

The official announcement of Russia's recent great scientific victory reads (in part) as follows:

"We, *Soviet people building Communism* [italics ours] have had the honour of being the first to enter into outer space. The victories in the exploration of the cosmos are regarded by us as not only the achievement of our people but also of entire mankind.

"We gladly place them at the service of all peoples in the name of progress, happiness and the well-being of all human beings on earth. We do not place our achievements and discoveries at the service of war but at the service of peace and security of peoples.

"On this solemn day, we address once again the peoples and governments of all countries an appeal for peace. May all people, irrespective of race and nation, colour, religious beliefs and social condition, devote all their efforts to safe-guarding stable peace throughout the world".

This is a most noble statement. We, as scientists, subscribe wholeheartedly to it and to the jubilation of Soviet Russia; indeed, we feel we have a share in it. Science cannot recognize national frontiers. There is no such thing as Communist science, or American science or British science; there is just *Science*. Moreover, present-day science is built up on science of the past (Sir Isaac Newton contributed largely to this latest Russian victory, three hundred years ago); and present-day science is the basis for the science of the future. Science, like other cultures, and disciplines, has been, is and will be in a state of evolution, and the pace of such evolution depends mainly on a host of genera and species of scientists, none of whom can afford to ignore the rest. While, therefore, reading with satisfaction the official Russian announcement, we think it is a pity that the words printed in italics were included. This great achievement is not a victory for Communism, any more than the great achievements in space research in America are a victory for democracy—in the political sense. All such achievements are the victories of science over Nature.

Conversely, it is equally disturbing to read that the news was received in the United States with "little surprise but deep disappointment", and that in Cape Canaveral a man working in the American space programme commented that the recent news from Russia "just makes me sick".

So, as a corollary, it is essential that we all realize that if the scientists and technologists do not get the sympathetic understanding and practical support they deserve, then those in political authority, coupled with their advisers, must accept the immediate blame; though the ultimate blame must rest on all those responsible for our education and for the mass dissemination and interpretation of knowledge.

One views with no little concern the utilization of science for political propaganda. The layman is not prepared for such news, and the majority of the public is in no position to evaluate the results. One otherwise quite intelligent person, on hearing the news, just commented: "I am now really afraid". It seems that the general public throughout the world is accepting as a fact that space research is now a race between Communists and the rest—mainly between the U.S.S.R. and the U.S.A. This cannot be a good omen for world peace, neither is it to the advantage of science in its dispassionate search for truth. The President of the United States has said that he is tired of being second in the space race with the U.S.S.R. Perhaps now, instead of making further efforts to become first, greater effort can be made by all the great Powers to arrange for a global pooling of scientific knowledge, thus forming the basis of H. G. Wells's ideal of a *World Encyclopædia*; but while there is so much political bad faith and open schism between countries, coupled with the hitherto tardy recognition that science is useful in peace as wel as in war, there seems to be little hope of such international collaboration. Moreover, it is futile to blame any one country for such refusal to collaborate, in spite of the fact that collaboration must be based on an all-or-none policy.

Despite the fact that the U.S.S.R. has been the first in some of the initial stages of space research (for there are undoubtedly many more stages to follow) it must be recognized that American contributions (though comparatively less spectacular and hence not having such 'hot' news or political propaganda value) to this now fashionable aspect of scientific research are by no means, therefore, of secondary importance. In fact, during these initial years, even if all data and results could be duly weighed and evaluated, it would be difficult to say which of these great Powers has contributed most, so far, to our knowledge of terrestrial and extra-terrestrial science; and since no one authority is in possession of all the facts it is virtually impossible to say which, from the scientific point of view, has done most towards the establishment and development of space research. Yet, in the long (perhaps very long) run, it will be the scientific assessment which really counts.

The kind of scientific competition, both inter- and intra-national, that we are experiencing to-day cannot be a healthy one. Claims for priority sometimes become quite nauseating. It is all bound to lead to misrepresentation, exaggeration, unfair claims, secrecy and consequently suspicion, and altogether general misunderstanding especially among the general public; and this provides fertile ground for political propaganda of the worst kind. (The Russian reports of even this latest feat are somewhat contradictory, and this has immediately had the effect among some people of querying the facts or wondering if some ancillary statements have been made deliberately to confuse the issue among other scientists of the world.) Apart from this, secrecy and surreptitious competition must involve wasteful and very expensive duplication of effort. Gone are the days when one could speak with pride, and justifiably take for granted, freedom in science; that is, freedom in research, freedom in discussion and debate, and above all freedom in exposition to the entire world of new scientific findings.

Lord Hailsham, the British Minister for Science, has said that it would be better and more economical to conduct inquiries concerning the Universe on an international basis. Most scientists, including, we think, many in the U.S.S.R., will subscribe to this view. But, as pointed out by Lord Hailsham, British development of full-scale manned space flight would be a misuse of scarce man-power and economic effort. We trust this will not be interpreted as a scientific dichotomy of the nations of the world into the 'haves' and 'have-nots', for that would be following the absurd propaganda of Nazi Germany. Rather would we accept Lord Hailsham's views and couple them with those of Mr. Harold Macmillan, who recently emphasized that scientific research is not confined to that of 'space'. In all branches of scientific research, for centuries, Britain has contributed its share—in some cases the lion's share; and history frequently puts Britain in the vanguard. Moreover, the urge among scientists to collaborate with each other, irrespective of nationality, is continually being emphasized by the large number of international scientific conferences held in many parts of the world.

Nevertheless, one must realize that the 'Iron Curtain' exists, even for scientists; and while that is allowed to continue to affect science, the humanities and other branches of cultural development there is bound to be a threat to the dignity of man and his very destiny.

It was Herbert Spencer who said that: "Science is organized knowledge". To-day, science has evolved well beyond that definition. However, even if we are prepared, in principle, to accept Spencer's aphorism we should modify it to read 'card indexed' rather than "organized". But, alas, the index cards are not all in the same file to which the entire scientific world may add and/or refer.

This makes all the more relevant and significant the comment made by Sir Bernard Lovell, director of the Jodrell Bank Experimental Station, when referring to this, the latest and greatest triumph of the scientists in the U.S.S.R.

"I think it is remarkable that a nation which was largely illiterate only a generation ago has succeeded in this immense task. It has done this because of the singleness of purpose and human sacrifice in material comforts on a scale unknown in the West.

"If the Western civilizations continue to disregard this example of the great results of investment in science, education and research, they will do so at their peril".

We do not advocate copying the methods in education being adopted in the U.S.S.R.; but we would urge that peoples of the world take note of this recent evidence of the result of encouraging science and scientists. That is best done, fundamentally, by giving sound scientific education to all, so that scientists will receive the encouragement they now lack, and when new scientific results are announced, the non-scientists (very much in the majority, and some in powerful authority) will, in consultation with the scientists themselves, take enthusiastic and intelligent note and be in a position to assess wisely and decide sensibly how such results shall be applied to the advancement of mankind.

At present, we seem to be paying only lip-service to the ideal that scientific achievements should transcend all political and racial barriers. For example, on several occasions during recent years, *Nature* has tried, through personnel of the Moscow Academy of Sciences, to persuade scientists of the U.S.S.R. not to persist in hiding their light under a bushel. But either they or their political superiors have so far turned deaf ears to such appeals. If the time does come when we have achieved that ideal, then shall we be able to congratulate those responsible for any notable scientific feat *because they are scientists*, not because they are members of any one nation or subscribers to any particular political creed.

A TREATISE ON ANALYTICAL CHEMISTRY

Comprehensive Analytical Chemistry

Edited by Prof. Cecil L. Wilson and David W. Wilson. Vol. 1*B*: Classical Analysis. Pp. xxii+878. (Amsterdam; Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1960.) 155*s*.

THIS book, Vol. 1*B*, comprises the second part of the first volume of this series on "Comprehensive Analytical Chemistry" which is being produced under the direction of an advisory board of acknowledged world experts in the various fields of analysis. This monumental scientific work is edited by Prof. C. L. Wilson and his brother, D. W. Wilson, both of whom are particularly eminent as microchemists and as teachers of the analytical method.

The first volume, 1*A*, has already received much well-merited eulogistic comment from readers and reviewers, and this second volume, dealing with classical methods of inorganic titrimetric and organic quantitative analysis, is also an extensive and scientifically detailed publication of the highest standard. The text is lucidly annotated where necessary and the reference bibliographies to each section are both helpful and comprehensive. The construction of laboratory apparatus is illustrated with great diagrammatic clarity, and the numerical tables and graphical representations form a most useful supplement to the text.

The theoretical and thermodynamical principles governing the analytical procedures are presented in much detail, and the academic student will welcome those extensive sections dealing with complexans, redox potentials, ionic equilibria, etc.

Much practical laboratory detail is also included in those descriptive parts relating to reagents, apparatus, methods, etc.; this makes the book singularly attractive to the young chemical analyst, who will find a wealth of experience and sound advice presented in a most assimilable manner. For the more mature analyst, there are descriptions of the recent modern techniques, of reagent standards, chelate compounds, a very extensive section on complexan reactions and titrimetry, potentiometric and amperometric methods, etc. The inorganic sections covers every titrimetric reagent normally used in the most up-to-date laboratory, and ends with an interesting note on the application of a miscellany of the more unusual reagents.

The section of the book dealing with organic quantitative analyses is equally comprehensive and detailed, both macro- and micro-techniques being described for the determination of the main elements, specific groups, etc. Various alternative methods are presented; for example, the determination of carbon gravimetrically as carbon dioxide, by acid titration after absorption in baryta, or by determining the change in conductivity of the baryta solution. All the usual non-metallic and metallic elements are covered, as are also the distinctive groups, nitroso, azo, thiocarbonyl, methoxy, alkyl, etc.

The volume ends with an excellent section covering titrations in non-aqueous solvents, a subject which is still one of the most attractive fields for those interested in pure research. The theoretical approach is again clear; aprotic, protogenic, protophyllic and amphiprotic solvents are discussed in relation to the Brönsted–Lowry–Lewis theories. Visual fluorescent, photometric, conductimetric and potentiometric indicator systems are described for various non-aqueous titrimetric determinations, and typical reaction phenomena are given graphical representation.

There is no doubt whatsoever that an authoritative, detailed and scientifically prepollent work of this nature will find its way on to the bookshelves of all institutions dealing with either the practice or teaching of analytical chemistry and will retain its status as a unique an alytical vade-mecum for many years to come.

D. T. LEWIS

FREE RADICALS IN AROMATIC SUBSTITUTION

Homolytic Aromatic Substitution

By G. H. Williams. (International Series of Monographs on Organic Chemistry, Vol. 4.) Pp. vii+133. (London and New York: Pergamon Press, 1960.) 45*s*. net.

INTEREST in homolytic, as distinct from heterolytic, reactions dates from the recognition by Prof. D. H. Hey in 1934 that the nuclear phenylation reaction, discovered some ten years earlier by Gomberg and Bachmann, did not conform with current ideas of aromatic substitution in terms of reactions by electrophilic and nucleophilic reagents. He postulated that this reaction represented a new type of aromatic substitution, involving electrically neutral free radicals. Further reactions displaying the same characteristics were soon discovered and were intensively studied. Homolytic substitution has since become a subject of considerable theoretical and practical interest.

In recent years, thanks to new and refined physical techniques, organic chemists have been able to accumulate reliable quantitative data on aromatic substitution processes of all types and this new knowledge has often necessitated a revision of theoretical concepts. The appearance of this monograph by Dr. Williams, a collaborator of Prof. Hey for many years, is timely, and it represents a valuable contribution towards a more comprehensive understanding of aromatic substitution generally.

The author subjects to critical scrutiny the various theoretical treatments, based on wave mechanics, which have been applied in attempts to rationalize the observed phenomena of aromatic substitution. Particular emphasis is placed on those aspects germane to the problems of orientation and reactivity in homolytic substitution. The limitations and deficiencies of these theoretical treatments are exposed. Thus, some unwarranted assumptions are made; for example, the failure to take cognizance of the intrinsic reactivity and polar characteristics of free radicals. Evidence, based on partial rate factors, is adduced to show that all homolytic substitution reactions exhibit some partial ionic character.

The reactions surveyed include homolytic arylation, both inter- and intra-molecular, alkylation, hydroxylation, acetoxylation, benzoyloxylation, amination and amidation reactions. In the case of mercuration, the author concludes that the case for a homolytic mechanism has not yet been definitely established.

Not unnaturally, in this rapidly advancing field, there are controversial issues and divergence of views among the various schools, British, American and German. The author projects his own views, but still manages to present a balanced statement, commendably free of any polemical bias.

J. IDRIS JONES

THE CARTESIAN MEDITATIONS

Cartesian Meditations

An Introduction to Phenomenology. By Edmund Husserl. Translated by Dorion Cairns. Pp. xii + 157. (The Hague: Martinus Nijhoff, 1960.) 9.50 guilders; cloth bound 13.25 guilders.

ALTHOUGH it would be idle to deny that Edmund Husserl did otherwise than stand—in a certain restricted sense—upon the shoulders of Descartes, yet the break-through to phenomenology as a rigorous system of pre-suppositionless philosophy was an achievement of the master himself. In the end it was almost independent of Cartesian influences. Hence the paradox of the title *Cartesian Meditations* and all that flows from them. But it was one of those symbolic events of history which brought Husserl to the Sorbonne in February 1929 to deliver a couple of lectures, afterwards elaborated into the work now under review. He truly meditated in Cartesian terms, producing out of this exercise his transcendental phenomenology.

This is scarcely the place to discuss the content of these lectures—that has already been attempted in a review of the German script some years ago. The immediate aim must be limited to welcoming such a scholarly and meticulous English translation as is now available in the present book. Anyone fortunate enough to possess Vol. 2 of *Husserliana* can follow for himself (since the pagination is carefully co-ordinated throughout by marginal brackets) the exact course of this transliteration, and the subtle changes of mood inherent in Husserl's thinking. In fact, the reader has the advantage of a transcription from the text now called *Typescript C*, where, as in most cases, this comes nearer to the author's works which were published during his life-time. Thus, it is possible for English-speaking scholars not only to recapture what happened in Paris more than thirty years ago but also to study it in the setting of the lecturer's habitual mode of presentation as his own thoughts developed. Our debt to Dr. Dorion Cairns is great, and only a little less to the publishers for making this classic of epistemology more widely accessible.

To follow Husserl's 'concluding word' in the original is very difficult. Here, it becomes a little easier, and its message for science more capable of assimilation. It is something like this: our practical daily life is naïve, engulfed in a series of happenings which are just there (an element of brute fact), and continue quite impersonally. It should be noticed that this immersion includes the act of valuing, something which it has become customary to exclude from the natural sciences, but which modern thought seems to be bringing back in a species of subjectivism akin to that of Husserl. This tendency is important for the biological disciplines wherein objectivity is less coercive than in the domain of mathematics. Yet for Husserl, all science is naïve to some degree, metaphysics included. But metaphysics as such are allowable under certain conditions.

The meditations end most appropriately with the well-known Augustinian exhortation: "Do not wish to go out; go back into yourself. Truth dwells in the inner man".

BIOPOESIS

Aspects of the Origin of Life

(International Series of Monographs on Pure and Applied Biology. Division: Modern Trends in Physiological Sciences, Vol. 6.) Edited by M. Florkin. Pp. viii + 199 + 5 plates. (London and New York: Pergamon Press, 1960.) 30*s*. net.

MOST of the papers given in 1957 at the Moscow international symposium on "The Origins of Life" (see *Nature*, 180, 886; 1957) were precirculated; corrected texts, together with the discussion, were published in 1960. The symposium was planned along tolerant lines, and many of the papers dealt with a range of themes that, though interesting and important for an understanding of present-day manifestations of life, had no necessary connexion with its origins.

In all symposia of this type, viruses and nucleic acids loom large—apparently for the reasons that lead shopkeepers, whatever they may ostensibly be selling, to run a line in ball-point pens as well. Here we have a usefully pruned version of the symposium; the clutter of papers on ephemeral fashions in biochemistry (which move more sluggishly than women's fashions but equally irrationally) has gone and the relevant papers remain.

There are five papers on the probiotic environment. These show so much interesting conflict that it is clear that astronomical and geological evidence leaves ample latitude for speculation. Even the widely accepted view that the primitive atmosphere was anaerobic may be questioned because the amount of ferric iron and oxidized sulphur in sediments shows that more oxygen passed through the atmosphere at a very early stage than is present in it now. Four papers deal with processes that may be analogous to those that formed organic matter initially. As the complexity of the mixtures subjected to various agencies—ultra-violet light, electric discharges, heat, etc.—increases, by the inclusion of hydrogen sulphide, hydrogen cyanide and other probable primitive effluvia, a fascinating range of products, with affiliations to most groups of molecules now important in biochemistry, will be made. Few theories of biopoesis should be excluded on the grounds that the substrates could not have been available.

The remaining papers deal with the evolution of enzymes, the role of asymmetry, photochemistry, and other themes. They are well selected, and one's only regret is that modesty led the editor to exclude his own excellent paper on the frequency with which substances that are used for one purpose in primitive organisms find a different application as evolution proceeds. If this were more generally recognized it would discourage dogmatic attempts to extrapolate back from present-day biochemistry to the primitive state of affairs.

N. W. PIRIE

Vacuum Technology Transactions

Proceedings of the Sixth National Symposium, also cumulative Author and Subject Indexes of 1954–59 Symposia. (American Vacuum Society Inc.) Under the Editorial Supervision of C. Robert Meissner. Pp. xvi + 335. (London and New York: Pergamon Press, 1960.) 120*s*. net.

THE symposium of the American Vacuum Society has become an annual event of international importance in the field of vacuum technology at which leaders in the subject from scientific and technological institutions, throughout the world, gather to read papers on their most recent researches. These papers are presented in detail in the *Vacuum Technology Transactions* which are usually published a few months after the symposium. The material covers almost every aspect of vacuum technology, from fundamental work of mainly academic interest to descriptions of the vacuum systems of the most recent particle accelerators and thermonuclear devices. The 1958 and 1959 volumes, however, show a noticeable increase in technological work directed towards the attainment of ultra-high vacuum in large machines. This is particularly true of the 1959 transactions, which include technical data associated with the design of the vacuum system for the Model *C Stellarator*, which will undoubtedly prove of great use to those facing similar problems. In addition to presenting the papers read at the conference, the 1959 *Vacuum Technology Transactions* contains a cumulative index of papers read at the previous symposia. The index is in chronological order, groups the papers in order of subject and is presented together with an author index arranged in alphabetical order, by year of presentation and page number. The combined index will be welcomed by those wishing to make a survey of recent research in a particular branch prior to embarking on work within the same field. The 1958 and 1959 *Transactions*, in keeping with the previous volumes, will be of considerable value to those who were not fortunate enough to be able to participate in the symposia and to those who wish to retain detailed information for future reference.

An Introduction to Electronic Theory of Organic Compounds

By H. L. Heys. Pp. 236. (London: George G. Harrap and Co., Ltd., 1960.) 16*s*. net.

THE writing of an elementary text-book is an art which is beset by difficulties. This is particularly true when the subject is the electronic theory of organic reactions. The evidence for electron shifts in molecules depends upon a wide variety of chemical and physical observations, and for an understanding of the significance of such measurements at least a thumbnail sketch of each method is desirable.

In developing his account of the subject the author has been aware of this need and he has been largely successful in his treatment of the problem. He has covered the main sections of the theory with an admirable conciseness and clarity, and the simpler aspects of any problem are clearly described without neglecting the minutiæ which may cause difficulties.

I am not, however, entirely in agreement with the author in devoting more than 20 pages to the Bohr and Sommerfeld treatments of the atomic orbitals, a discussion which seems to have no relevance to the remainder of the book. Moreover, some details included in the text do not seem to be in agreement with recent information. Thus, the idea that the two carbon-carbon bonds of ethylene have different energies is a theoretical concept rather than an experimental observation (p. 49). Also (p. 87) the value of 190 kcal./gm. atom $C_{(S)} \rightarrow C_{(g)}$ (^3P) has never been seriously supported.

The book is well produced with clear diagrams and a generous index. The only errors in production noted by the reviewer are 'C' for 'Cl' (last line of p. 78), a spacing error (line 10, p. 106) and the loss of a bond in tropolone (XXV, p. 110). These can be easily put right in the next edition.

R. I. REED

The Veterinary Annual, 1960

Edited by W. A. Pool. Second year. Pp. xxiv + 359 + 32 plates. (Bristol: John Wright and Sons, Ltd., 1960.) 42*s*.

THE literature now being published on every aspect of veterinary science is so voluminous, and it records so many important advances in knowledge, that everyone who has to try to keep pace with it will welcome the appearance of a second volume in this authoritative series. For it gives us, under the able editorship of W. A. Pool, an epitome, selected by 35 specialists, of the important work done since the publication of the first volume of the series in 1959.

The field covered by veterinary research is nowadays very wide, and even a brief study of these pages will show how closely modern veterinary research is integrated with the work of other branches of science. Though the book is mainly for the veterinarian, it reflects the many facets of the study of comparative medicine and surgery, and it will for this reason interest all who are concerned with disease, whether they be medical men, especially perhaps those who are co-operating with the veterinarian, or chemists or others who provide us with so wide an array of drugs and other compounds used in the battle with disease. The nomenclature of these compounds is, as the editor puts it, 'harassing' to many who have to try to understand their composition and uses, and welcome features of this book are the appendixes to the articles on drug therapy and on insecticides and acaricides, which give, together with the chemical names, the trade or proprietary names used for them in different countries.

For those who are interested more in the general aspects of progress of veterinary work there are special articles on veterinary medicine in the United States, the Netherlands and France, written by experts in these countries, an article on veterinary medicine in the British Colonial Territories, two others on the challenge of *Brucella* and on the poultry industry and—graceful reminder of the interests of youth nowadays—a well-written and practical article on "The Child, the Pony and the Veterinary Surgeon". The Secretary of the Royal College of Surgeons contributes an article on legal matters affecting the veterinary profession, and there are chapters on new drugs and appliances and a list of new English veterinary books and new editions.

This book, like its predecessor, should be in every library concerned with the study and control of disease, and it is to be hoped that nothing will prevent the appearance of future volumes in the series.

G. LAPAGE

GENERATION OF ELECTRICITY WITHOUT THE USE OF ROTATING MACHINERY

By Dr. K. H. SPRING
Central Electricity Generating Board, London

A COURSE of lectures on direct processes for the generation of electricity has recently been given at University College, London, under the above title. An introductory survey was given by me. The main object of the lectures was to give an idea of the scientific principles and possibilities, rather than to describe the engineering of devices.

The principles of many of the direct processes have been known for a great many years, but the recent rise in interest is probably attributable to several factors. It seems likely that advances in efficiency above about 40 per cent of the heat engines (steam or Diesel) used for large-scale power generation will be achieved only with extreme difficulty. There is a possibility that some of the new processes may ultimately permit a major advance in generation efficiency to be made, and also lead to a lowering of capital costs. New requirements for electric power for military and other specialized uses, such as operation in remote sites or in space-vehicles, have created a demand for compact, simple, and in some cases silent, devices in which the relatively low conversion efficiency so far attained is not of great economic consequence. A further factor is that in recent years advances in technology and physical understanding have enabled new classes of materials with interesting electrical properties to be developed.

The classical effects of an electric current are magnetic, chemical and thermal, and, in the reverse process of generation, it is only the first of these—moving a metallic conductor in a magnetic field—that has been used at all widely. A number of generation processes can now be listed, some of them based on direct chemical and thermal effects. The first three (or possibly four) of these may ultimately be developed sufficiently to supplant or supplement present methods of large-scale generation, but the others are likely to be of specialized application only.

(1) The Fuel Cell

This is an electrochemical device in which the processes occurring are almost the converse of those in electrolysis. Fuel (usually in the form of a gas) is fed to one electrode, and an oxidant to the other. The electrodes are separated by an ion-exchange membrane or an electrolyte which ensures that only ions can move from one to the other, balance being maintained by the flow of electrons, constituting the current, in the external circuit. Because the free chemical energy is released by a directed flow of ions, and not by degradation into a random thermal motion of molecules, the fuel cell acts isothermally and escapes the Carnot limitation inherent in all heat engines. Consequently, the apparent thermodynamic efficiency may be very high—more than 90 per cent. However, as soon as any current is drawn from the cell there are ohmic and polarization losses which lower the open-circuit voltage, just as they do in a primary battery. The fuel cell is usually operated at a current density that gives an efficiency in the region of 60–70 per cent.

Apart from various exotic fuels and oxidants that may be used for special purposes, hydrogen and oxygen (or air) are most easily ionized and combined at temperatures around 20–200° C., and the work of Bacon at Cambridge, and of Shell and other companies, is well known. For central power generation, hydrogen even if impure is too expensive a fuel, and for economic parity with conventional methods it would be necessary to use the cheapest possible gas based on total gasification of coal, or on re-formation of oil products. The use of such a gas requires further development of a high-temperature fuel cell, using a molten salt electrolyte which is stable to carbon monoxide and dioxide, rather than the simple aqueous alkaline electrolyte of the Bacon cell. Research on such cells is being actively pursued in many countries.

(2) Magnetohydrodynamic (MHD) Generation

This is the name which is now employed to denote direct extraction of electrical energy from a fast-moving conducting fluid passing through a magnetic field. The principle is similar to that of an electromagnetic flowmeter which measures the voltage developed between the ends of a conductor moving in a magnetic field. A gas which has been raised to a temperature high enough for some thermal ionization to take place, say 2,500° K., may be used as the working fluid, the conductivity being raised still further by 'seeding' with a low work-function material such as potassium. The upper temperature is limited by the combustion process itself, and also by problems of combustion chamber and duct materials. At the highest temperatures envisaged only a fraction—less than 1 per cent—of the molecules are ionized. The possibility of generating power at appreciable efficiencies, therefore, depends on the transfer of kinetic energy from the uncharged particles to the ions and electrons which alone interact directly with the magnetic field, and thence by some mechanism to an external circuit. Very high gas velocities, of the order of Mach 1, are also needed. Supersonic working would allow higher efficiencies to be attained, but would pose difficult aerodynamic problems.

Because of their high mobility, most of the current in the plasma is mediated by electrons rather than ions and in a continuously acting device electrodes must be provided to maintain charge equality. It is difficult to conceive of electrodes that will emit for long periods in an atmosphere charged with combustion products, and a system of pulsed or cyclic working which will permit inductive coupling may be necessary. The use of electrodes may be feasible in a clean working fluid which is heated indirectly, for example, by a nuclear reactor. Further research may suggest ways in which ionization can be obtained at lower temperatures by non-thermal means. This would be helpful from the point of view of materials, but would be less attractive thermodynamically.

(3) Thermionic Generation

This implies the 'boiling-off' of electrons from a heated cathode surface to a nearby, cool, anode. (A very small current may be obtained from a diode valve with the heater emitting, but with zero anode voltage.) The separation between the electrodes must be extremely small in a vacuum diode (about 0·01 mm.) to minimize the effects of space charge in limiting the current. Such a small separation may not be practicable on a large scale, and attention has therefore been devoted to alternative methods. Most of these are based on the injection of ions into the inter-electrode space. Cæsium in contact with a hot cathode surface readily ionizes, and such cæsium diodes are sometimes described as plasma thermocouples, by analogy with the more usual solid-state thermocouples.

A thermionic generator is a heat engine, and its efficiency is limited to that of a Carnot cycle operating between the temperatures of the cathode and anode. The former should therefore be as high as possible, consistent with the desired life of the diode. In practice, the thermal radiation loss from the cathode to the anode is a factor seriously limiting efficiency. The use of crossed electric and magnetic fields which guide the electrons from one electrode to the other may reduce space-charge effects and also permit geometries which minimize radiation losses. The voltage developed by a diode depends on the difference in work-function between the cathode and anode. One advantage claimed for cæsium injection is that it reduces the anode work function. Development of maximum power depends on proper matching of the load.

(4) Thermoelectricity

Both the theory and practical applications of thermoelectricity have made tremendous strides in the past few years—due in large measure to Joffe. The usefulness of a thermoelectric material depends on three factors—the thermoelectric (Peltier) coefficient α, and the electrical conductivity σ, which should be as large as possible; and the thermal conductivity K, which should be as small as possible. The 'figure of merit' $Z = \alpha^2\sigma/K$. For metals, in which the electrons are nearly free, α is low—only a few μV./deg. C., but in some semiconductors α can be much higher. The three factors contributing to Z are not independent. To obtain the highest value of Z in a semiconductor, the material is prepared, either p- or n-type, by 'doping' to optimize α to a value in the region 200 μV./deg. C. It is found that the highest value of Z which can be achieved depends on the temperature at which the material operates, and ZT gives a truer impression of usefulness. (T is the absolute temperature.)

The value of σ/K is nearly fixed, being determined by the Wiedemann–Franz ratio in metals. In semiconductors the crystal lattice contributes to the thermal and electrical conductivities; it seems likely that it will not be possible to reduce the lattice (or 'phonon') contribution to less than that of the electrons, which would limit ZT to 4, corresponding to 37 per cent of Carnot efficiency for a given temperature-range. In the most advanced materials now available, it is several times higher, and the best values of ZT are about 1 for both p- and n-type materials, corresponding to about 15 per cent of Carnot.

Moderate voltages may be generated by arranging alternate p- and n-type materials which are thermally in parallel, but electrically in series.

(5) Thermomagnetic Generation

If two coils, of which one (the primary) is carrying a current, are wrapped around a core of ferromagnetic material, the flux linkage with the secondary will change if the permeability of the core changes. Thus, an alternating voltage may be induced in the secondary if the core is temperature-cycled around the Curie point. In a sense this may be regarded as a form of parametric amplification of the signal in the primary, the required energy being provided thermally. Gadolinium, with a Curie point of 27° C., has sometimes been suggested as a useful, if expensive, material to use where a source of heat a few degrees above normal ambient temperatures is available. There has been some controversy over the efficiency of the generator. It appears that quite high Carnot efficiencies can be obtained in the immediate neighbourhood of the Curie point, but a range of, say, 20° C. between source and sink may correspond to only 3° on the specimen. This, coupled with the fact that, to cover any large temperature-range, cascading is needed, makes thermomagnetic generation in practice compare very unfavourably with thermoelectric.

(6) Ferroelectric Generation

It is possible to generate voltages of the order of 1,000 by making use of the variation with temperature of the permittivity of a ferroelectric material, such as barium titanate. The material is made the dielectric of a capacitor, which is charged at its Curie temperature at which its permittivity is maximal, through a small battery via a holding diode. If the temperature of the dielectric is changed, the capacitance falls, and the voltage rises, since the diode prevents loss of charge. The permittivity of a dielectric under electric stress is nearly constant at all temperatures below the Curie point, so it is necessary to cycle it from the Curie point to a temperature above it. Again, this method can be regarded as a form of parametric amplification of the input signal supplied by the battery. Circuits have been developed so that, at any instant, a number of capacitors are in different phases of the thermal cycle, and only a small initial charging is needed: this forms a convenient method of generating high voltages for use in space vehicles.

(7) Photovoltaic Converters (Solar Cells)

The earliest type of photovoltaic generator is represented by the selenium photocell, which had a conversion efficiency of about 0·2 per cent when exposed to sunlight. Its modern counterpart, of silicon, has been developed largely as a result of research on transistors. Its action depends on the penetration of radiation to a p–n junction, so the cell is in the form of a disk of n-type material, on the top of which is diffused an extremely thin p layer.

The photovoltaic cell somewhat resembles the thermocouple in embodying *p–n* junctions; but the physical mode of operation is rather different. The former depends on photons penetrating to the junction with sufficient energy to raise electrons from the valence band to the conduction band. Since the forbidden energy gap (activation energy) of silicon is 1·1 V., the radiation must be shorter in wave-length than about 1μ. However, because some electrons are attached to impurity atoms, and are therefore more nearly free, there is some response at wave-lengths beyond the quantum cut-off. The efficiency of present solar cells is about 15 per cent to sunlight, so that 150 W./m.^{2} may be generated at sea-level in clear weather. As the present cost is about £10,000/m.^{2}, only very specialized applications can be considered. Cells based on more advanced materials such as gallium arsenide and cadmium telluride may possibly attain efficiencies of about 25 per cent.

(8) Piezoelectric Converters

When magnetic or electric fields are applied to certain materials there are dimensional changes, and the converse is also true. Thus, when pressure or shear forces are applied to some types of crystal (for example, quartz) a potential difference is created, and this is the principle of operation of some types of gramophone pick-up. Recently, synthetic materials have been developed suitable for the generation of very high voltages and one of the best now available is 'PZT', a solid-solution ceramic of lead titanate–zirconium titanate. Its piezoelectric coefficient is such that a voltage gradient of about 10 kV./in. is produced for a pressure of 1 ton/in.^{2}. The maximum pressure that can be withstood for repeated rapid stressing is in the range 1–5 ton/in.^{2} so that voltages of 20 kV., suitable for petrol engine ignition systems, can be produced from quite small pieces of material by direct pressure and without the intermediary of coils or breakers. Piezoelectric generation is a method for converting mechanical to electrical energy, and therefore is not in competition with other methods for direct generation from heat or fuel. Nevertheless, it is likely to revolutionize the design of electric ignition systems on vehicles.

MECHANISMS OF EXPRESSION OF GENETIC INFORMATION

By WENDELL M. STANLEY, JUN., and PROF. ROBERT M. BOCK

Department of Biochemistry, University of Wisconsin,
Madison 6, Wisconsin

DURING several years past, the overall pattern of protein synthesis has become fairly well established. This pattern indicates that the genetic information inherent in the chemical structure of deoxyribonucleic acid (DNA) is in some way incorporated into the structure of ribonucleic acid (RNA), which then possesses the capability, in the presence of suitable precursors, of guiding the polymerization of specific sequences of amino-acids into protein[1]. We have considered mechanisms by which the DNA may be able to carry out such communication mediated by RNA with the rest of the cell.

It is well documented that a molecule of DNA is composed of two strands, one of which is the reciprocal of the other in a base-pairing sense[2]. For this reason, the information in a single DNA molecule is actually repeated, once in each strand. However, it may quite well be that the cell is only able to 'recognize' one of these information strands, at least so far as the polymerization of an RNA molecule is concerned. This would be the net result of either of the two following mechanisms: (1) RNA synthesis is directed by the two-stranded DNA duplex, but can proceed in one direction only; or, (2) RNA synthesis is directed by a single DNA strand, but only one of the strands is capable of serving as a template. This type of restrictive mechanism might result from the same sort of chemical restraints which give the enzyme polynucleotide phosphorylase its unusual specificity with respect to the polymerization of cytidylic residues as compared to guanilic residues[3].

A second alternative, which is functionally equivalent to the above, is to suggest that both DNA strands are capable of coding RNA, but that one of the two RNA strands produced cannot code protein, either because it is left in a form vulnerable to cellular ribonucleases, or because it becomes stabilized in a non-functional ribonucleoprotein complex. This alternative can also be applied to the case in which both RNA strands are capable of coding protein, but with the additional condition that one of the product proteins be regarded as non-functional or non-resistant to proteolysis. This suggestion, which states that one of the two possible RNA strands derived from a DNA molecule cannot make a 'good' protein, is quite logical when one considers that a point mutation in the original DNA duplex will necessarily change both the RNA strands and consequently both their possible product proteins. To expect that evolutionary selection would preserve both proteins in a functional form is not reasonable, in view of current knowledge on the manner in which amino-acid sequence directs protein structure.

The last and most attractive alternative for the communication of information contained in DNA is to postulate that each strand of the DNA duplex directs the synthesis of an RNA molecule complementary to itself. The difference between this alternative and that already discussed arises when we consider what the cellular environment can do with these two reciprocal RNA molecules. We suggest that one of these molecules, on separation from its DNA parent, encounters a specific protein which has both a tendency to aggregate with molecules like itself and a high affinity for certain regions in the

RNA. This affinity may be explained by the ability of this protein to recognize a certain specific sequence of bases repeated at intervals along the RNA molecule. However, it is apparent that mutations affecting this sequence would not destroy its recognizability so long as the general character of these sections is preserved. Thus, evolution might well have modified these repeating regions into sections of similar character the function of which would not be dependent on an absolute sequence. In any event, the RNA-protein complex so formed 'crystallizes' to form microsomes or ribosomes—structures which permit the exposure of the coding bases functional in the sequential ordering of specific amino-acids. This 'crystallization' of the ribosomal protein with its RNA may well be the basis of the mechanisms for the separation of RNA from its DNA parent. (If a similar specific affinity of an aggregating protein occurred for a strand of DNA, this could provide a mechanism by which the small, single-stranded DNA viruses select one strand for building into the nucleoprotein and exclude the other.)

The second RNA molecule, possessing a base sequence reciprocal to that of the molecule already discussed, will not have this affinity for the ribosomal structural protein. However, it could possess an affinity for a second type of protein, which may well be the protein which binds soluble RNA (*S*-RNA) and which is characterized by having the activity of the amino-acid activating and transfer enzymes. However, due to the lack of interaction of this type of protein with itself, this ribonucleoprotein (RNP) is not compact and resistant to cellular hydrolytic enzymes. It is therefore cleaved at all those points where the protein attachment does not protect it, and thus gives rise to a large number of RNP molecules. It is postulated that this family of small RNP molecules can now be acted upon by enzymes which have evolved in the cytoplasm. Certain of these enzymes will trim away parts of the ends of the bound RNA, others will link these modified RNP molecules with nucleotides such as 5-ribouridilic acid, and others will add nucleotides such as cytidylcytidyladenylate to the 3′-end and to the 5′-end nucleotides such as guanidylate, giving rise, finally, to a molecule which has the properties of the amino-acid activating enzyme – *S*-RNA complex, and which further contains within its nucleotide structure those base sequences which are reciprocal to certain regions of the ribosomal RNA. Thus, this *S*-RNA is automatically equipped with nucleotide sequences capable of pairing both with the enzyme activating the amino-acid and with that section of the ribosomal RNA corresponding to the reciprocal sequence of bases which specifies the particular amino-acid.

This hypothesis provides a clear and internally consistent mechanism for the efficient utilization of both strands of information of the DNA, and, further, a mechanism for the synthesis of both soluble and ribosomal RNA. It predicts phenomena which should be usable in testing the hypothesis ; namely, the synthesis of *S*-RNA should not occur without the dependent synthesis of ribosomal RNA; and, assuming equivalent efficiency or 'turnover numbers' of the two complementary DNA strands (this RNA could be modified in quantity but not in quality by the efficiency of the appropriate protein in stripping the RNA from its DNA parent), the induction of a specific family of RNA, such as occurs upon the virus infection of a bacterial cell, should lead to the production of ribosomal and *S*-RNA, the next neighbour patterns of which when tested with isotopically labelled phosphate should follow the same reciprocal rules that have been found for double-stranded DNA[4]. This hypothesis may also offer reasons for various phenomena which have not as yet been satisfactorily explained. For example, it is known that there exist organisms which do not seem to have any of their DNA molecules in common[5], but which still appear to be able to synthesize similar, if not identical, proteins. Using our postulated mechanism of information transfer, this would be explained by assuming that those regions of the DNA responsible for the sections of RNA concerned with the recognition of ribosomal structural protein could differ markedly between two organisms, and thus, even though their equivalent DNA molecules carried the same encoded message, the DNA composition could vary within wide limits. Thus, the same 'code' between nucleic acid and protein can be used in all organisms, without demanding that their DNA molecules be identical. A second problem which may be partially answered is that of the development and intracellular recognition of DNA molecules derived from individual chromosomes. We suggest that each chromosome has its own general repetitive base sequence ; this sequence again being that responsible for the sections of its RNA which have the function of recognizing the ribosomal protein. This would provide a definite distinction between DNA molecules produced in differing chromosomes; a distinction which may be used by the cell to retain DNA molecules within their proper chromosomes through an interaction with the chromosomal protein. This postulate could be tested by the banding, in a high-resolution density gradient[6], of the DNA isolated from organisms with a small number of chromosomes, and observing whether the number of bands is correlated with the number of chromosomes or linkage groups.

We possess little information on the nature of the precursors of the elaborate genetic forms we see to-day—too little to permit any detailed speculation on the early stages of evolution. Nevertheless, the reader may enjoy, as we have, speculating on the way in which a short primitive polynucleotide double strand, one-half with an affinity for peptide which aggregates readily, and the other strand with an affinity for a poorly specific peptide catalyst of polymerization reactions, could provide a base upon which mutation could play until more elaborate forms of life resulted.

After we submitted this manuscript, Prof. G. H. Echols kindly brought to our attention an earlier proposal of one of the above mechanisms for producing template RNA and amino-acid-transferring RNA[7].

THE 2-METRE UNIVERSAL REFLECTING TELESCOPE OF THE GERMAN ACADEMY OF SCIENCE, BERLIN

By Dr. RUDOLF JOBST
VEB Carl Zeiss, Jena

ON October 19, the Government of the German Democratic Republic placed at the disposal of the German Academy of Science a 2-m. universal reflecting telescope, which was designed and built by VEB Carl Zeiss of Jena, and inaugurated on that day in the newly erected Karl Schwarzschild Observatory in Tautenburg, near Jena.

The 2-m. universal reflecting telescope is outstanding as a type and represents the first and largest of its kind in the world. Embracing four different optical arrangements, the new telescope provides for the entire field of present-day astronomical and astrophysical work and the problems which are likely to arise in the future. The optical systems are interchangeable and conveniently adaptable to certain specific problems of observation and, in each instance, afford the same high performance as would a correspondingly large telescope individually built for the respective type of observation.

Thus, for investigation of extra-galactic objects, such as the structure of the Milky Way, as well as for the compilation of routine astronomical observations, the new telescope embodies the Schmidt system with the 2-m. spherical main mirror and 1·34-m. correction plate, with a 4-m. focal length and an aperture ratio of 1 : 3. In this form the Schmidt system of the telescope represents the largest in the world. It permits photographs 24 cm. × 24 cm. to be taken of portions of the stellar regions about 11 square degrees in size.

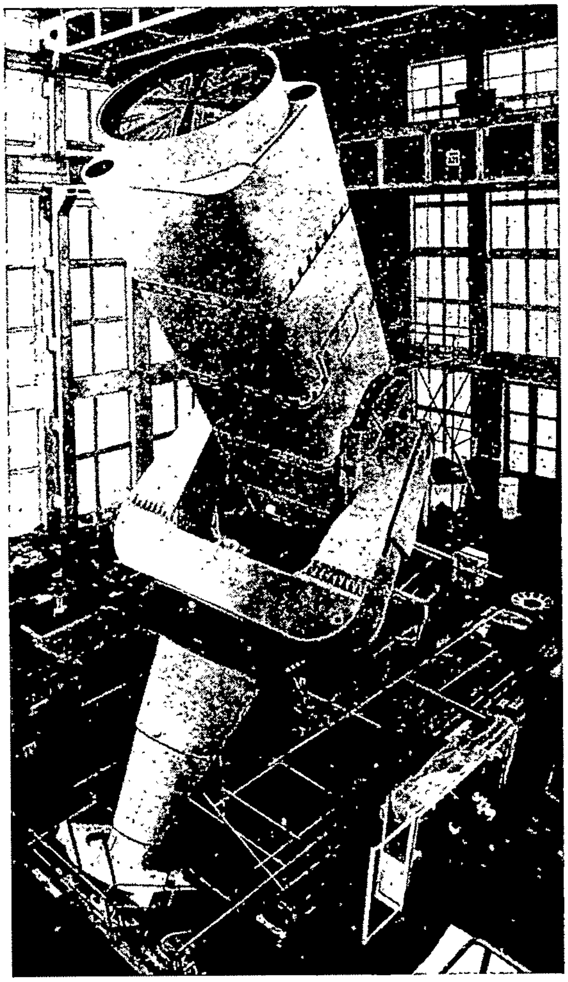

Fig. 1. The 2-m. universal reflecting telescope in the assembling department for astronomical telescopes of VEB Carl Zeiss, Jena

For the individual examination of cosmic gas clouds, distant spiral nebulæ and other faint objects in the universe, the quasi-Newtonian system with its high light-gathering power is employed, for which the full aperture of the reflector is used. In this case a small lens-correction system is interposed immediately in front of the image plane in order to compensate for the errors which a spherical concave mirror produces when used in this way.

With the quasi-Cassegrain system of the new reflector telescope, spectrographic investigations of fixed stars may be carried out down to the faintest luminosities, predominantly by photo-electric photometry and spectrography. Owing to the effective 20-m. focal length of this system, the examination of single stars is possible even in regions of greatest stellar abundance. In the quasi-Cassegrain system a super-hyperbolically deformed convex mirror 400 mm. in diameter is used with the 2-m. concave mirror.

The quasi-coudé system, with the same optical arrangement, but with another convex mirror of greater light-gathering power, and with a 92-m. effective focal length, permits, with the stationary focal image and with spectrographs for the highest dispersions, the study of the fine structure of the spectral lines of stars. Through one of the two bearing journals of the telescope tube, and through the large horseshoe mount, the optical path is conveyed via other plane deflecting mirrors down to the lower end of the main axis of rotation, which is aligned parallel to the Earth and is diverted into the spectrographs located in well-isolated rooms in which constant temperature and humidity are maintained. Astronomical and atomic physicists are using this equipment for research in which both are interested. Indeed, the cosmos affords them research facilities far beyond those available in experimental laboratory activities.

Mechanically, the telescope consists of a square-sectioned tube of about 10 m. length on a horseshoe mounting (Fig. 1). The moving parts of the telescope weigh 65,000 kgm., and therefore special arrangements, including a hydraulic bearing, are used for following the movement of the stars with the necessary accuracy. The telescope floats on an oil film 0·05 mm. thick and is moved with the required accuracy by means of a precision worm-gear 2,160 m. in diameter, the teeth of which deviate from the mean theoretical interspace by less than 0·5 sec. of arc.

The movement of the 26,000 kgm. tube about the declination axis, as also about the polar axis, is via a 'Selsyn' transmitter conveyed to a central control desk and several side desks, whence the instrument may be set entirely electrically for the astronomical co-ordinates of celestial bodies. By means of a number of compensation devices the adjustments and seatings of the optical parts of the telescope in different positions are preserved at maximum accuracy under varying temperature conditions.

The 2-m. main reflecting mirror, weighing 2,370 kgm., as well as the correction plate of thickness 38 mm., and the different auxiliary mirrors, were cast by the VEB Jenaer Glaswerk Schott and Gen., which also attended to part of the preparatory work. What must be looked upon as outstanding performances in the province of astronomical optics are the correction plate, made of glass transparent to ultra-violet radiation and the two Cassegrain and coudé-counter mirrors, the mirror surfaces of which depart from a sphere by no more than 0·05 mm.

The Zeiss spectrographs, which are still in the manufacturing stage, will be equipped with diffraction gratings capable of producing stellar spectra up to a maximum length of 1,500 mm. At the inauguration of the Tautenburg Observatory, the Soviet Academy of Science presented to the Observatory one of these diffraction gratings, in addition to those produced by VEB Carl Zeiss.

The 2-m. universal reflecting telescope and all its appurtenances are housed in an observatory dome 20 m. in diameter and of a total weight of 175 tons, built by VEB Carl Zeiss. The building is heat-insulated, thus effectively preserving the night-temperature within the dome in day-time, despite solar radiation and other heat effects to which the dome may be exposed. Adverse fluctuations of temperature are avoided in this way, or are at least considerably diminished.

While work with this new 2-m. universal reflector telescope has been successfully begun at the Tautenburg Observatory, three more reflector telescopes of the same dimensions are in the process of construction in the Jena Zeiss works at Jena, two for the U.S.S.R. and one for Czechoslovakia. These instruments will benefit by the experience which had been collected during the development, construction and testing of the Tautenburg telescope.

A CHEMICAL BASIS FOR THE CLASSIFICATION OF ANIMAL VIRUSES

By Dr. P. D. COOPER

Director, Virus Culture Laboratory, Medical Research Council Laboratories, Carshalton, Surrey

BESIDES satisfying the intellectually tidy, an efficient taxonomy is useful and necessary because it emphasizes resemblances which make worthwhile generalizations apparent, and makes minor differences easier to understand. The possible objection that viruses may not form a single natural taxonomic group need not inhibit attempts to define one. Several systems have in fact been proposed to classify animal viruses[1,2] but have not proved very suitable, and virologists have generally agreed on the need for more data.

However, the earlier systems were based mainly on habitat at the level of the intact animal (that is, host-range, type of tissue usually affected, host-response and type of lesion produced, or vectors), and this now seems a major fault, since many objections can be levelled at such a primary subdivision[3]. For example, 'obviously' different viruses (foot-and-mouth disease and cow-pox viruses) can produce somewhat similar lesions, albeit at opposite extremities, of the same animal. Host-animal reactions may vary with the one virus (for example, chickenpox and herpes zoster[4]), and are a very complex expression of growth at the cellular level. Viruses can often be adapted to unusual hosts without much difficulty. Grouping by known hosts seems an arbitrary procedure, since many hosts may be unknown and thus only a few of the creatures potentially infected are selected; again 'obviously' different viruses (for example, myxoma and yellow fever viruses) can both depend on a similar vector (mosquitoes). Tissue tropism can be genetically very unstable; poliovirus can mutate in one step from neurotropic-plus-viscerotropic, to purely viscerotropic, and back again[5], and host-range variants of encephalomyocarditis virus are easy to obtain by a single growth cycle[6]. Cultured cells normally resistant to intact poliovirus can nevertheless support maturation of virus if infected with ribonucleic acid extracts of infected cells[7]. Adenoviruses have been found in stools[8], and might therefore legitimately be called 'enteroviruses', along with poliovirus.

It is therefore very doubtful whether habitat, as defined above, is at all suitable as a primary criterion for classification of animal viruses, although, as discussed below, it may be useful at another level of emphasis.

All systems of biological classification depend on mutationally stable criteria; indeed, the closeness of all biological relationships might in time be judged by the number of mutations which separate them, although this reasoning is easier to accept for the present when applied to sub-species and to interrelated micro-organisms. The difficulty with viruses is that they are genetically unstable when judged by human time-scales, appearing in a state of rapid evolution, so that a classification denoting species and genera is difficult to apply[9]; attempts at a quantitative appraisal of the genetic differences without emphasizing one criterion more than another are likely at present to run into difficulties for lack of data.

What is needed to provide a lasting system for the classification of viruses is to obtain some primary and secondary sub-divisions which are not too arbitrary and which ought to be genetically quite stable. It is the purpose of this article to emphasize the need for genetic stability, and to point out the utility of a formal system based on lines of thought already familiar to many virologists, the high genetic stability of which, however, is possibly not fully appreciated as a classification criterion.

Nucleic Acid as Primary Criterion

The basis of the system proposed is the chemical structure of the 'virion'[10], that is, the largest free-existing infective unit which can be defined as a single virus particle (usually the infective unit occurring naturally in largest numbers). It is primarily concerned with the type of nucleic acid contained, since this is the one component always essential for the production of infective virus; the chance of interconversion of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) by simple mutation is vanishingly small, if not impossible, so that this criterion should be quite stable. Another advantage is that this criterion must apply to all viruses, yet in an exclusive way. Present genetic concepts demand that a virus must contain either RNA or DNA or conceivably both; if the psittacosis group is excluded, the existence of both in any virus is doubtful, but the possible presence of RNA in a DNA-containing virus (for example, the pox group) need not affect the classification proposed. The only ambiguity may arise in the hypothetical case where the same total of information can be carried by either DNA or RNA in a single form acceptable to a host cell, thus giving two phases for the same virus. Fortunately consideration of this objection can be deferred until it can be raised experimentally. It is submitted that the terms 'RNA virus' and 'DNA virus' are terminologically improper; to avoid the clumsy phrases 'ribonucleic acid-containing virus' and 'deoxyribonucleic acid-containing virus', the terms 'ribovirus' and 'deoxyvirus' are suggested.

Essential Lipid as Secondary Criterion

The secondary sub-division uses the criterion of ether sensitivity, suggested for classification purposes by Andrewes and Horstmann[11]. Destruction of infectivity by lipid solvents (which appears to be correlated with sensitivity to low concentrations of detergents[12,13], and in the case of Newcastle disease virus[14] with sensitivity to lipase) presumably reflects the presence of fatty components essential for infectivity. Those viruses insensitive to ether and detergents either do not contain lipid (for example, poliovirus[15]), or their lipid content is tightly bound or not essential (for example, vaccinia[16]). The genetic stability of this criterion is less certain than that of difference in nucleic acid content, but two facts suggest that it is non-trivial and that it should be fairly stable (that is, not readily lost by non-lethal mutation): (*a*) the ether-sensitive particle of influenza virus breaks down completely when the lipid is removed[17]; (*b*) among riboviruses, the sensitivity to ether correlates with maturation at the cell wall[18], suggesting a widespread mechanism involving lipid materials without which the viruses cannot become infective.

In practice and excepting the pox group, viruses appear either to be quite stable to ether, or to be very sensitive (provided that they are tested in an accessible state and not protected within a mass of tissue), making it a fairly easy criterion to apply. Those ether-resistant viruses so far examined (for example, poliovirus[19], adenovirus[20], polyoma virus[21]) have a strong and regular lattice-like (clathrate) substructure, whereas the ether-sensitive viruses are less rigid[22], tending also to flatten more in electron microscopy. Accordingly, the terms 'clathrovirus' and 'lipovirus' are suggested for the ether-resistants and ether-sensitives respectively, to apply to the infective form only (as some lipoviruses, for example, herpes virus[23], may contain clathrate substructures).

Consideration of Major Groups

When these two types of separation are made, and the viruses the positions of which are known then arranged in each of the four major subdivisions in order of size, a considerable degree of order results (Table 1), and the viruses are brought together in groups which are often immunologically related. Four principal chemical relationships are therefore used: nucleic acid type, content of essential lipid, size and immunological character; it will be noted that 'chemical' is here used in its widest sense, and that among entities of the size of viruses there is little difference between chemical content and fine morphology. There will, of course, be gaps, many known viruses cannot yet be placed, and the placing of some viruses (marked with a query) is based on rather slender data, but the position of most is reasonably well based for at least one member of a serological group.

It will be noted that the pox-viruses are treated as a special case, and this is for two reasons. First, separation into ether-sensitive and ether-resistant has the effect of separating myxoma/fibroma from the vaccinia and avian-pox groups[11], and, although there are some reservations about their relationships[24], recent work[25,26] shows their closeness by reactivation and serological data. Secondly, vaccinia nucleic acid clearly replicates in the cytoplasm[27], whereas the nucleic acid of all other viruses adequately studied (herpes virus[28], adenovirus[29], encephalomyocarditis[30] and fowl plague[31]) replicates in the nucleus. The pox viruses therefore seem metabolically more autonomous than smaller viruses, and there is a strong case for regarding them as a distinct group intermediate between the smaller viruses and the ornithosis group.

Because of its inherent genetic stability the nucleic acid type is preferred as a primary criterion, and, because of its observed genetic instability in some cases, immunological character is set last, but the relative stability of the other characters is not predictable. The viruses also come together in groups of similar habitat, and it may be that this admittedly useful grouping, while unsuitable as a primary criterion, could be applied as a tertiary one.

Deoxyviruses are generally larger than riboviruses although overlap does occur. Lipo-riboviruses tend to be larger than clathro-riboviruses. Thus some generalizations can be made from this system, since the primary and secondary criteria also separate other properties, and this should help the understanding of the structure and growth mechanisms of new viruses if these criteria can be applied.

Table 1. A Classification Scheme for Animal Viruses based on Nucleic Acid Content, Sensitivity to Ether or Detergents, Size and Serological Relationships

						Diameter (mμ)
ANIMAL VIRUS	DEOXYVIRUS (DNA-containing)	Pox-virus	Ether sensitive	Myxoma Fibroma		
			Ether resistant	Animal pox * (vaccinia, etc.) Avian pox * (fowlpox,etc.)		200–300
		Smaller deoxyvirus	Lipovirus (ether sensitive)	Herpesvirus	Simplex *B* pseudorabies	120–150
				Measles ? Rinderpest ? Canine distemper ? } *		
			Clathrovirus (ether resistant)	Adenovirus *		70–90
				Rabbit papilloma		40–50
				SE polyoma		40–50
	RIBOVIRUS (RNA-containing)	Lipovirus (ether sensitive)		Myxo-virus	*NDV*, mumps, parainflu. *	80–120
					Influ. *A*, swine influ., fowl plague *	70–80
					Influ. *B*	
				Rous sarcoma ?		70–80
				Vesicular stomatitis ?		70–80
				Certain arthropod-borne viruses	*A* (*EEE*, Semliki forest, etc.) *	40–50
					B (West Nile, Murray Valley, etc.) *	30–50
		Clathrovirus (ether resistant)		Vesicular exanthema, Reovirus (*ECHO* 10)?		50–70
				Certain entero-viruses	Poliovirus * *ECHO* 8 Coxsackie *A*7, *A*9, *B*1, *B*4, *B*5 Talfan, Teschen	27–32
				EMC, ColSK, *MM*, Mengo *		27–32
				Foot-and-mouth disease		22–25

* Serological group. Data on vesicular exanthema from Shaffer and McClain (personal communication)

Conversely, other properties can help classification when the criteria cannot yet be applied. For example, the large size of measles virus[32], the formation of large intranuclear inclusions and its intracellular mode of growth all suggest that it is a deoxyvirus. Rous sarcoma[11] and vesicular stomatitis viruses are both lipoviruses; there is evidence, not firmly based, that both are riboviruses, and their continuous mode of release[33,34] strongly supports this idea.

At the moment there appears little evidence to contra-indicate the classification of Table 1, although other arrangements are possible; for example, one may regard size as more important than ether sensitivity and promote it to secondary criterion, but the large differences in size among the smaller viruses makes deciding the border-line arbitrary and inconvenient. From a practical point of view, determination of reaction to ether is much easier than determination of size. Good evidence against the proposals would be the finding of strong serological relationships between the main groups differentiated in Table 1.

Correlations with Growth Properties

The separation into four main groups accords well with growth properties, where these are known. In fundamental replication mechanism (that of the nucleic acid) one must expect deoxyviruses to resemble one another more than riboviruses, and vice versa, although a possible exception to this is the small single-stranded DNA-containing phage[35], the replication of which may resemble a ribovirus. The deoxyviruses (vaccinia, herpes and adenovirus as examples) are slow to mature and to be released, and form marked inclusion bodies, but the riboviruses mature much faster and do not form marked inclusions.

The lipo-riboviruses (for example, vesicular stomatitis, influenza, Western equine encephalomyelitis, fowl plague) appear to be matured at the cell wall[18], whereas the clathro-riboviruses mature internally (for example, poliovirus, encephalomyocarditis, foot-and-mouth disease, vesicular exanthema), probably in the cytoplasm. This differentiation does not apply to the deoxyviruses, which all mature internally, but in this case the core of a lipovirus (herpes), although being formed in the nucleus, receives a final coat (and therefore is matured ?) on entering the cytoplasm[28], whereas a clathrovirus (adenovirus) appears to be completed in the nucleus[29].

It is interesting that viruses capable of causing proliferative lesions, even if finally necrotic, occur in all groups except the clathro-riboviruses; hæmagglutinins of one sort or another are also found in all groups except the lipo-deoxyviruses, indicating that neither of these phenomena is related to a particular virus type, and is therefore *per se* of small value for classification purposes.

Means of including more Viruses

It may be felt that it is impractical to determine the nucleic acid present in a large number of viruses in order to classify them, even if one selects only a single member from each serological group. However, this information is urgently necessary, since it is an essential preliminary to understanding the most fundamental part of their growth processes, representing probably the most important single datum, and providing a most useful guide to selecting models for study.

The most direct way of determining the nucleic acid is to examine the purified particle, but this is probably also the most lengthy, as some viruses, particularly the small thermolabile ones, are difficult to purify. Fortunately, there is at least one apparently conclusive and fairly direct short cut. This is to obtain the nucleic acid in an infective form susceptible to nucleases (usually as the free acid), and then to determine its sensitivity to the two species of nuclease. This has now been done with poliovirus, encephalomyocarditis, mengo, Eastern equine encephalomyelitis, Semliki forest, West Nile, Murray Valley encephalitis and foot-and-mouth disease viruses among the riboviruses, and polyoma[36] among the deoxyviruses, and also for the DNA-containing bacteriophages T_2 (ref. 37) and $X174$ (ref. 38); some viruses have so far proved resistant to successful extraction, but may yield to improved techniques.

A more readily applied, if less direct, method[39] is to test the growth-inhibitory effect of 5-fluorodeoxyuridine, which should specifically inhibit DNA synthesis. This compound inhibits growth of a deoxyvirus (vaccinia) but not of a ribovirus (poliovirus), and gives promise of reliable results provided that it can be confirmed with more known examples and that it is used with a host cell which it penetrates successfully (that is, in which it inhibits a known deoxyvirus). This is a very simple test, and there is a strong case for all virus laboratories to run it through their collection of virus strains, as the information to be obtained is of primary importance. A preliminary screening of new clinical isolates, for example, with 20 per cent ether and 5-fluorodeoxyuridine, might speed typing and economize in antisera.

Classification of all Viruses

It is tempting to follow this scheme to its conclusion and include all viruses in the one classification, since superficially plant and bacterial viruses seem separated from animal viruses only by host range. This would have the effect, satisfactory from a structural point of view, of placing all bacteriophages and Tipula iridescent virus alongside the adenoviruses, and plant viruses (for example, tomato bushy stunt virus[40]) with poliovirus; the embarrassment of deciding the correct 'kingdom' for plant viruses which grow in insects (and vice versa) would be avoided. In fact, the fundamental likeness in all biological replications and cellular metabolism makes it nowadays legitimate to question seriously whether the usual separation into plant, animal and bacterial viruses is justified, because this classification may depend only on relatively trivial differences in the virus coating. Convincing evidence of this would be growth of a virus in a host of the 'wrong' kingdom; this might be achieved by unusual manipulative techniques, provided that there is no fundamental impediment. Alternatively, evidence for such an impediment would itself constitute most important information.

Conclusions

In summary, a taxonomy for animal viruses based on type of nucleic acid and essential labile lipid content appears less arbitrary and genetically more stable than those previously suggested, and may provide a useful means of ordering the host of viruses now newly coming to light. The typing of the nucleic acid, a factor of primary importance, is likely to be easier than was hitherto supposed, requiring not very accurate assay procedures but needing some system in which infectivity can be detected; it merits wide consideration. Such a taxonomy might in time include all viruses.

OBITUARIES

Prof. H. R. Dean

PROF. HENRY ROY DEAN, professor of pathology in the University of Cambridge since 1922 and Master of Trinity Hall during 1929–54, died on February 13, a few days before his eighty-second birthday.

Head-boy of the School at Sherborne, he gained first-class honours and, later, an honorary fellowship at New College, Oxford. He qualified from St. Thomas's Hospital, and was then elected to a senior demyship at Magdalen College, Oxford. Thereafter, on a travelling fellowship, he worked in Berlin with Wassermann. In 1912, he became professor of pathology and bacteriology at Sheffield; and in 1915 professor of pathology and dean of the Medical School in Manchester. He was appointed professor of pathology at University College, London, in 1922 but, before taking up this post, moved instead to Cambridge as professor of pathology there.

Dean's published contribution to medical research was not voluminous, but it laid solid foundations for much of our present knowledge of immunology. His work on complement continued the classical line of Bordet and Wassermann. His work on the precipitin reaction made a quantitative approach to this subject possible. His description of the pathology of anaphylactic shock in man has not been

PHYSICS DEPARTMENT [illegible]

surpassed. His realization of the essential unity of the antibody reactions helped to bring order into a confused field. His papers, like those of his great predecessors, are classical in quality, commendable to students.

His second great contribution to medical science was the quality and nature of his teaching. Forty years ago, he was a very great teacher, who insisted on the interdependence of all branches of pathology and medicine. He made his students eager to know more and more about more and more. Pathology he regarded as one great subject, of which bacteriology, immunology, virology, hæmatology and morbid anatomy were all interdependent parts, and liable to suffer from individual elevation to specialist rank. He taught pathology as the true basis of all medicine and as especially valuable for the insight it gave into normal function. He was, thirty and forty years ago, a brilliant lecturer; but his greatest effect was obtained when demonstrating in the laboratory.

His creation of the Part II and Part I Pathology Triposes in Cambridge has benefited many generations of Cambridge medical graduates, and, through them, the whole of medicine.

As a principal leader in the Cambridge Medical School, as Master of Trinity Hall and, during the two difficult and anxious years which preceded the Second World War, as vice-chancellor, Dean's energies were necessarily devoted chiefly to administration. Outside Cambridge, he had many activities; at various times, and for many years at a time, he was chairman of the council of the Imperial Cancer Research Fund, secretary of the Pathological Society of Great Britain and Ireland, a member of the Royal Commission on the University of Durham. He served on the General Medical Council as representative of the University of Manchester during 1919–22, and of the University of Cambridge during 1942–57.

He received several honorary degrees—LL.D. of the Universities of Aberdeen and Western Reserve, honorary D.Sc. of the University of Liverpool. He was a Corresponding Fellow of the New York Academy of Medicine.

Dean was no dilletante, but he was well informed on a very wide range of subjects. To accompany him on a wine-buying expedition for the College; or to handle and appreciate some of the silver he had collected; or to inspect his seedling viruses in Trinity Hall; or to climb mountains with him, or swim with him, or to follow the boats in Mays or Lent races, or sit with him on boards and committees, or hear him quote Horace with a conscientiously archaic pronunciation, or just to drop in for a chat with him—these were all memorable experiences, and for the memory of them one is grateful. But one is chiefly grateful for the example of staunch, objective honesty of outlook on everything that came within his ken, and for the irrepressible humour of his commentary on it. An anonymous contributor to *The Lancet* has said "I owe it to him that I have had such an interesting life". Many others would acknowledge the same debt.

In 1908 he married Irene Wilson, who died in 1959, after being his close partner and perfect counterpart throughout a long joint career. Mrs. Dean shared the affection and regard in which he was held by many hundreds of younger people whom they helped, encouraged, guided and entertained.

E. T. C. Spooner

Prof. Jerome T. Syverton

Jerome T. Syverton, whose death occurred on January 28, began an outstanding, active career in microbiology as an instructor in bacteriology at the University of North Dakota in 1928. Born in Courtenay, North Dakota, in 1907, he entered the University of North Dakota in 1923, obtaining the A.B. degree in 1927 and the B.S. degree in 1928. He graduated from Harvard University School of Medicine in 1931, and after an internship and assistant residency in medicine at Duke University Hospital in 1931–32, he became an assistant in pathology and bacteriology at the Rockefeller Institute for Medical Research, New York. There he obtained basic knowledge in virology under the guidance of Dr. P. K. Olitsky, and in 1932 became a member of the faculty of the University of Rochester School of Medicine and Dentistry.

Except for a sabbatical leave in 1942 at Vanderbilt University School of Medicine as visiting associate professor of pathology and bacteriology, Syverton's fundamental and pioneering work involving, for example, tumour viruses and multiple viral infections of single animal cells, as well as the development of his outstanding skill as a teacher and student adviser, was done during 1934–47 while in the Department of Bacteriology at the University of Rochester. For his outstanding research in virology, he received the Lilly Award in Bacteriology and Immunology in 1938. During 1944–46 he was on active duty in the United States Navy as a visiting investigator at the Rockefeller Institute, and member of Naval Medical Research Unit 2 in the Pacific Theatre. In 1947 he became professor and head of the Department of Microbiology at Louisiana State University School of Medicine, and since 1948 had been professor and head of the Department of Bacteriology at the University of Minnesota.

During his academic career Syverton's enthusiastic and vigorous approach to professional life, with simultaneous devotion to his family and friends, set an extraordinary example for students and associates. His graduate and postdoctoral students during twelve years at the University of Minnesota alone numbered more than 65. His productivity as an investigator was remarkable, and during 1957–58 he was recipient of the Commonwealth Fund Award for Creative Work. Eighty-seven articles describing his own work and 119 in conjunction with his students and associates were published between 1933 and 1960. His stature in science and academic medicine was evidenced by his membership of many scientific advisory committees, and his enthusiastic support of science at an international and national level was widely recognized and appreciated. The world's scientific community has lost a creative and productive investigator, the educational community an enthusiastic teacher, the community of his colleagues and associates a true friend, and his family an affectionate and lovable father.

William F. Scherer

Prof. B. Davison

Physicists and mathematicians connected with the British and Canadian atomic energy projects have learned with regret of the sudden death of Boris Davison on January 24, while still a very productive mathematical physicist engaged on problems of neutron transport.

He was born in Gorky on July 10, 1908, and educated in Russia. He graduated from the University of Leningrad in 1931, and was engaged in hydrology for about seven years thereafter. Through his English grandfather he had a tie with England, and when in 1938 he was requested either to renounce British nationality or leave the U.S.S.R. he elected to go to England. He worked for a short period with Prof. L. Rosenhead, but his health broke down. After a considerable period of convalescence he joined the atomic energy research team at the University of Birmingham under Prof. R. E. Peierls, in 1942. His powers as a mathematician enabled him to make many important contributions, particularly to neutron transport theory, a subject which was to occupy most of his attention for the rest of his life. For some of this work he was awarded the Ph.D. of the University of Birmingham in 1944.

His connexion with Canada started when he joined the Montreal Laboratory of the joint United Kingdom–Canadian Atomic Energy Project in 1943. His association with the late Dr. G. Placzek was a very fruitful one, and he accompanied Drs. Placzek and Mark to Los Alamos. He moved to the new Chalk River Laboratory as a member of the United Kingdom staff in the Theoretical Physics Branch and in 1947 returned to England to work at Harwell. In 1954 he joined the staff of the Computation Centre in the University of Toronto, lectured in numerical analysis and reactor physics and was appointed associate professor of physics in 1960. For the past six years he served Atomic Energy of Canada, Ltd., as a consultant. His knowledge, experience and talent have contributed in many ways to the technical success of the Canadian Atomic Energy programme.

In 1957 his book on *Neutron Transport Theory* was published: it established him publicly as the authority in this subject to which he brought a remarkable combination of analytical power and precision, an uncommon facility in numerical analysis and physical perception. Not only has he expounded the methods of other mathematicians but he has also delineated carefully the boundary of the region within which they can be effectively applied. In his preface he was generous in acknowledging assistance, but those who knew him know well his patience and the exacting standards he set for himself.

Much of Davison's work was concerned with improving mathematical representation of nuclear processes in reactors and with the associated computational problems. He was a ready inventor of algorithms for computing and for avoiding pathological conditions in large calculations.

He was a gentle, shy man, painstaking, kind and generous in helping his fellows, but intolerant of pretence. His intellectual life was not confined to the subject of his specialty. He had a broad, modern interest in science and he liked poetry.

He is survived by his wife Olga.

W. H. WATSON

NEWS and VIEWS

The First Manned Earth-Satellite, 1961μ

THE spaceship-satellite *Vostok*, launched from the U.S.S.R. at 06.07 U.T. on April 12, carried the first man to make a journey in orbit about the Earth, Major Y. A. Gagarin of the Soviet Air Force. The satellite, which weighed 4,725 kgm. (10,417 lb.) excluding the final-stage rocket, was projected into an orbit inclined at 65° 04′ to the equator, and having an orbital period of 89·1 min. Its height above the Earth varied between 175 km. at perigee and 302 km. at apogee. The satellite, designated 1961μ1, made one revolution about the Earth: its deceleration by retro-rocket motor began at 07.25 U.T. and the cabin was safely and successfully brought to Earth in the U.S.S.R. at 07.55 U.T., close to the pre-determined area. The satellite's radio transmissions were on frequencies of 9·019, 20·006 and 143·625 Mc./s. It is reported that on his historic flight Major Gagarin was able clearly to see coastlines, mountain ranges and large cities, and that to him the Earth appeared light blue in colour against a very dark sky. The final-stage rocket, 1961μ2, which separated from the satellite, remained in orbit for several days.

Major Yuri Alekseyevich Gagarin

The Henry Draper Medal: Dr. M. Schwarzschild

DR. MARTIN SCHWARZSCHILD, professor of astronomy, Princeton University, has been awarded the Henry Draper Medal of the U.S. National Academy of Sciences for his work in the field of stellar evolution. Dr. Schwarzschild was born in Potsdam, Germany, in 1912, and took his Ph.D. degree in astronomy at the University of Göttingen in 1935. He was a Research Fellow at the University of Oslo during 1936–37 and at Harvard College Observatory during 1937–40.

In 1940, he went to Columbia University as a lecturer on astronomy and was appointed assistant professor in 1944. Joining the faculty of Princeton University in 1947 as a professor of astronomy, he was appointed to the Eugene Higgins chair of astronomy in 1950. Dr. Schwarzschild is widely known as the director of the Project Stratoscope, in which the surface of the Sun was photographed from an unmanned balloon some fifteen miles above the Earth's surface. Analysis of the data obtained from these photographs contributed much towards the understanding of the mechanisms of heat transfer from the centre of the Sun to its surface. For this work Dr. Schwarzschild and two of his colleagues received the Newcomb Cleveland Prize of the American Association for the Advancement of Science in 1957. Also of great importance are Dr. Schwarzschild's computations of the evolutionary track of stars and his study of their internal composition. He is a faculty member of Princeton's James Forrestal Research Center Program in Advanced Physics, and a member of the U.S. National Academy of Sciences.

Theoretical Physics at Birkbeck College : Prof. D. Bohm

PROF. DAVID BOHM, whose appointment is announced to the new chair of theoretical physics at Birkbeck College, London, is well known among physicists as the originator of the Bohm–Pines theory of collective motions in a plasma. He is known to a wider public for his views on the philosophy of science, particularly his criticisms of the interpretation of quantum theory advocated by the school of Niels Bohr. Prof. Bohm, who was born in the United States, was educated at Pennsylvania State College, California Institute of Technology, and the University of California. During the Second World War he worked (for the U.S. Atomic Energy Project) on the electromagnetic separation of isotopes. After the War he became assistant professor at Princeton, and later professor successively at Sao Paulo, Brazil, and the Technion, Haifa, Israel. Since 1957 he has been on the staff of the University of Bristol. He is a physicist of great inventiveness and imagination, whose stimulus and leadership have set several others on the pathway to success in theoretical physics.

Harvard Museum of Comparative Anatomy

PROF. ERNST MAYR has been appointed director of the Harvard Museum of Comparative Zoology as from July 1. Founded by the great nineteenth century naturalist Louis Agassiz, the Museum is one of the very few major centres of natural history research in the United States. The present director, Dr. Alfred S. Romer, who has guided for the past fifteen years the Museum's growing eminence as a centre for the study of animal life, past and present, will continue to teach and do research at Harvard. Both Romer and Mayr hold Alexander Agassiz professorships at the Museum. Prof. Mayr has made important contributions to evolutionary theory during the past thirty years.

Staff College for Further Education

MR. W. J. RICHARDS, director of the Royal Radar Establishment, Malvern (see *Nature*, 172, 277; 1953), has been appointed the first director of the proposed new Staff College for Further Education by the Governing Body, set up by the Minister of Education last autumn under the chairmanship of Lord Fleck. Mr. Richards will take up his new appointment in July. The aim of the College is to create a national centre at which principals and other selected staff from colleges of technology and commerce can exchange ideas and experience with senior staff from industry, local and central government, the universities and overseas, and where they can jointly study the aims, ideas and the growth of education in the light of the rapid advances in science and technology. A capital fund of £100,000 has been contributed by industry to meet the initial expenses of founding the College, and the Minister of Education has undertaken to contribute an annual grant towards the running expenses. The College is to be entirely residential and a search is being made for suitable premises, preferably in the Midlands, around which the College can be developed.

Harkness Fellowships of the Commonwealth Fund

THE following have been included in the recent appointments to Harkness fellowships of the Commonwealth Fund: J. N. Ball (Liverpool), zoology; J. P. Cornford (Trinity, Cambridge), sociology; J. E. Everett (Clare, Cambridge), geophysics; B. M. Funnell (Trinity, Cambridge), oceanic geology; J. V. Greenman (Gonville and Caius, Cambridge), theoretical physics and applied mathematics; J. M. Hollis (New College, Oxford), philosophy; D. H. P. Jones (Christ's, Cambridge), astronomy; M. C. Scott (Birmingham), nuclear physics; J. J. Turner (King's, Cambridge), infra-red spectroscopy; E. G. Wilson (King's, Cambridge), physics. The following were included in the awards from Australia and New Zealand: N. Sneath (Melbourne), engineering; J. J. Veevers (Sydney), geology. Ten fellowships have been awarded to candidates from France, Italy and the Netherlands.

Commonwealth Students in British Universities

IN a written answer in the House of Commons on April 11, Mr. B. R. Braine, Joint Under-Secretary of State for Commonwealth Relations, stated that in July 1959, 3,457 students from the Commonwealth overseas were studying, in United Kingdom universities, the applied sciences to which paragraph 55 of the report of the Commonwealth Education Conference relates. In the academic year 1959–60, this number was 3,338, but figures for 1960–61 are not yet available. More places are expected to become available for such students as the total number of places in United Kingdom universities increases, but the exact number of additional places which would be taken up in 1961–62 cannot be forecast. In 1958–59, 177 students from the Commonwealth overseas were enrolled for full-time research at United Kingdom universities in agriculture and forestry; 130 in dentistry; 1,475 in medicine; 1,608 in technology; and 67 in veterinary science; for 1959–60, the corresponding figures are: 202; 145; 1,477; 1621; and 93. On April 13 a written answer by the Minister of Education, Sir David Eccles, gave the number of Commonwealth students in colleges of further education in England and Wales as 7,203 in the current session, compared with 6,493 in 1959–60. In the present session, the number of Commonwealth students in technical colleges is 477, an increase of 25 on 1959–60.

Employment of Scientists in Government Services

MOST of the March issue of *State Service*, the journal of the Institution of Professional Civil Servants, is occupied by the annual report of the Association; but the general secretary, Mr. Stanley R. Mayne, directs particular attention to the difficulty experienced by the Ministry of Aviation in filling posts at principal scientific officer-level as an example of the reluctance of scientists to enter the Scientific Civil Service. The press advertisements only produced five applications, and only one of these was judged worth interviewing, and he was not good enough to be selected. The Department had four other candidates, of whom three were selected and offered appointment but the only applicant from industry declined the offer. Three other scientists were afterwards interviewed and two were selected; one of these has already resigned. The annual report for 1960, which records a membership of 53,923, quoting the figures for recruitment of scientists from the recent report of the Civil Service Commission which are causing the Commissioners grave disquiet, is critical of the value of information collected by the Civil Service Pay Research Unit other than as a broad basis for discussion.

Valuation and Rating of Scientific Institutions

THE annual report for 1960 of the Parliamentary and Scientific Committee (Pp. 22. London: Parliamentary and Scientific Committee, 1961) contains a concise summary of the addresses and discussions during the year and of Dr. J. Killian's speech at the annual luncheon. It refers also to the European Parliamentary and Scientific Conference sponsored by the Committee, with the financial support of the Council of Europe, the Organization for European Economic Co-operation and the Foreign Office, in London, during March 21-23, 1961. The Rating Sub-Committee has again considered the position of scientific societies, and at a meeting on December 5 it was agreed to seek amendments to the Rating and Valuation Bill to secure that hereditaments given mandatory 50 per cent rating relief under clause 8 (1) include all hereditaments properly established for scientific purposes, and that the power given to rating authorities to reduce or remit the payment of rates chargeable in respect of such premises should be transferred to the Ministry of Housing and Local Government so that there should be central decision. It was also agreed to seek similar mandatory 50 per cent relief for all organizations qualifying for freedom from income tax under section 449 of the Income Tax Act, 1952 (relating to research associations).

Smithsonian Institution

THE annual report for 1960 of the United States National Museum is as usual a well-illustrated, bulky volume giving details of much curatorial work, an impressive account of research undertaken by, or in collaboration with, the staff, and a list of donors and their gifts covering nearly 2,500 accessions (Pp. vi + 175. Washington, D.C.: Government Printing Office, 1960). The modernization programme started about a decade ago continues in all departments, and the construction of the Museum of History and Technology is in progress and will be completed by March 1962. The building has been designed so that the collections will be shown under the best known modern conditions, and also maximum flexibility within the structure for future development has been a prime consideration. In geology events such as the development of jaws and the transition of life from water to land have been demonstrated by diagrams and models. Among the unusual specimens displayed are a 14-ft. skeleton of the predatory Cretaceous fish *Xiphactinus*, and a slab from New Mexico showing the crowded bones of the amphibian *Buettneria*, entrapped in an evaporating Triassic swamp.

The British Leather Manufacturers' Research Association

THE annual report for 1959-60 of the British Leather Manufacturers' Research Association records a membership of some 75 per cent of the productive industry with a net increase in membership of 15 and a total income of £70,134, including a grant of £21,900 from the Department of Scientific and Industrial Research (Pp. 70. Egham, Surrey: British Leather Manufacturers' Research Association, 1960). An effluent liaison officer and assistant analyst have been appointed to recommend and demonstrate modifications in leather-making processes designed to reduce effluent problems, and a new radioisotope research laboratory has been built, particularly for the study of chrome complexes in leather by radioisotope techniques. The report of the Director of Research refers to the maintenance of fundamental research on the constitution and properties of collagen and other constituents of hides and skins, the chemistry of vegetable tanners and the mechanical and elastic properties of collagen and leather fibres. In the enzyme unhairing of hides a bath-treatment at 80° F. for three days ensured consistent removal of short hairs with the long hairs, and small-scale trials indicate that no great difficulties should be experienced in vegetable tanning. An investigation of the factors in chrome-tanning processes which are important for satisfactory dyeing has commenced, and the leather properties which are required for good acceptance of pigment finish and good coverage are being investigated; investigations are being made on suede leather with the view of improving the colour fastness, particularly of black suede. Work on the adaptation of semi-chrome upper leather for moulded-sole footwear continued, but mechanical engineering work was discontinued and engineering work will be limited to chemical engineering topics, including effluent problems. Work on the deterioration of leather by heat, moisture and perspiration has led to substantial advances in an understanding of the deterioration of leather by perspiration; but in work on waterproofing of leather the study of laboratory testing methods now has priority, and an extensive testing programme in connexion with sheepskins and sheepskin leathers has been necessary. Besides outlining the programme of research, the report includes a list of publications during the year.

The Cawthron Institute

THE annual report for 1959-60 of the Cawthron Institute, Nelson, New Zealand, records some changes in the scope of the Institute's research activities, and its facilities for investigating the more fundamental aspects of plant nutrition have been extended by new equipment (Pp. 35. Nelson, N.Z.: Cawthron Institute). The Director's report reviews the progress of pasture research, hop research and tomato research at the Institute and of the chemical investigation on the constituents of the tobacco leaf responsible for variations in quality. Besides a list of publications, the report includes five short special articles. E. T. Chiltendon describes investigations on bitter pit in apples ; E. B. Kidson, chemical investigations on tomato plants in water culture ; D. J. Stanton, further experiments on the treatment of tomato seedlings with *n-m*-tolylphthalamic acid ; T. B. C. Christie, the effect of fertilizer applications on the *Phytophthora* disease of hops ; and R. J. Monk, work on alkaloids and smoking quality of tobacco.

The Brotherton Library, Leeds

The annual report of the Librarian of the University of Leeds, for the session 1959–60, records holdings at July 31, 1960, of 479,157 volumes and 179,215 pamphlets, of which 334,099 volumes and 117,306 pamphlets are in the Brotherton Library (Leeds: The Brotherton Library, The University. Pp. 12. 1960). Accessions during the year totalled 15,842 volumes, 3,281 pamphlets and 31,907 periodical parts. Loans to readers numbered 116,739 and inter-library loans 1,814 books borrowed and 3,449 lent. The report refers briefly to the extension of the Brotherton building proposed in the University Development Plan published in May 1960 which contemplates incorporation of an additional bookstack for 400,000 volumes, together with further reading rooms and larger administrative quarters, and a separate building for undergraduates with space for 800 readers and 30,000–50,000 volumes. The proposals are being studied and, meanwhile, a further investigation of undergraduate use of library services is being made.

Raw Materials of Ceramics

In *The Museums Journal* of March 1961, Mr. P. J. Adams describes an exhibition which was arranged to mark the occasion of the Seventh International Ceramic Congress and suitably modified will form a permanent feature at the Geological Survey and Museum, London. The exhibition is divided into three sections reflecting the main branches of the British ceramic industry: (1) pottery and whiteware; (2) structural clay-products; and (3) refractories and technical ceramics. Each section consists of a simple wall-type display with a single waist-high bench for the geological and ceramic specimens and a back-screen for narrative text, geological maps, photographs and diagrams. The nature, geological occurrence and methods of exploitation of the raw materials are briefly described and their processing and utilization are summarized.

Selenium Poisoning

Selenium poisoning is known to be a disease of domestic animals in the United States. Wheat, corn and milk produced in western and southern districts of the United States contain small quantities of selenium. Animal and vegetable foodstuffs from the United States make up an increasing part of the diet of Japanese school-children and this has led to investigations into experimentally produced selenium poisoning in various animals (*Yokohama Med. Bull.*, 11, No. 5; October 1960). The investigations were carried out by Hiroshi Tsuzuki, Kazuhoshi Osawa and Takashi Hosoya of the Department of Hygiene, Yokohama University School of Medicine, Yokohama, and showed that selenite had the greatest toxicity among animals. It disturbed the body weight, tibial length and physical strength of animals when it was given intraperitoneally and orally. Inhaled selenium vapour disturbed physical functions, but the toxicity varied because of varying degrees of selenium in the air. Metallic selenium, which was given orally, disturbed digestive functions temporarily and greatly influenced gain in weight and physical strength; it suppressed the development of tibial length only slightly. Selenium in ointment, rubbed on the skin of animals, caused a remarkable dermatitis, and a decreased gain in weight, but there was only slight suppression of tibial length and physical strength. Generally, females were more disturbed physiologically and developmentally than males. The second generations which were born from poisoned mothers seemed to have higher resistance to selenium than other animals.

Internal Carotid Artery Occlusion

In recent years, internal carotid artery occlusion has been diagnosed frequently in young adults. A study by John G. Humphreys of the Department of Medicine, University of Toronto, and T. H. Newton, Department of Radiology, University of California, of seventeen patients of less than 40 years of age with carotid occlusion shows how the underlying mechanism accompanying the occlusion may differ from that in older patients in whom the cause is atherosclerosis (*Brain*, 83, Part IV ; 1960). There were thirty-three older patients whose carotid occlusions occurred after the age of 40. There was little difference in the sex incidence of the younger group compared with the predominance of males in the older group. Eleven of the seventeen patients in the younger group either had lesions adjacent to the carotid artery or had evidence of a generalized systemic illness at the time the carotid occlusion was diagnosed. Four of the thirty-three patients of more than 40 years old had similar complicating factors. The complications of both groups included trauma, aneurysm, tumour, pregnancy, and inflammatory diseases. Hypertension, diabetes and atherosclerotic involvement of other major arteries were noted in only one of the seventeen younger patients, but were present in thirteen of the thirty-three older patients. The prognosis for survival following an internal carotid artery thrombosis is better in patients of less than 40 years of age.

Dietary Fats and Cholesterol

In recent years the number of people dying from the sequelæ of vascular diseases has been as great in the Netherlands as highly industrialized countries. The influence of various dietary fats on the blood cholesterol content has been investigated by F. S. P. Van Buchem, J. J. Speelman, A. A. Idema, A. T. Valkema and H. J. Thomasson, and is reported in the recent *Proceedings of the Royal Netherlands Academy of Sciences* (Series C. Biological and Medical Sciences, 44, No. 1; 1961). The twenty test subjects were physically healthy, were mentally defective and were constantly under clinical and dietetic supervision. Before the test diets were given, the spontaneous variations of the serum cholesterol-level of most test subjects were studied for several months. The test diets used only differ from normal diets in that different fats, but in the same amounts, were given. If maize oil was used as a fat, the serum cholesterol-level fell in all of them, but it rose on cocoa fat feeding. The influence of various mixtures of maize oil and cocoa fat was also studied. The phospholipid content of the blood fell also with maize oil, but not so strongly as the cholesterol-level. The influence on the neutral fat differed in the various test subjects. The cause of this rise or fall of the serum cholesterol-level has not been determined.

New Species of Rotifer

FROM a pool (*p*H 6–6·5) on Cawston Heath, eleven miles north-east of Norwich, a hitherto undescribed *Collotheca* sp. with only four coronal knobs has been taken occasionally since 1957. This rotifer takes its place in the list with the two four-lobed members of the genus so far recorded, namely, *Collotheca quadrilobata* (Hood) and *C. monoceros* (Zacharius). H. G. S. Wright, in an article appearing in a recent issue of the *Journal of the Quekett Microscopical Club* (Series 4, 5; No. 13; 1961) regards this as a doubtful identification, the description and figure given by Zacharius strongly suggesting a mutilated *Stephanoceros fimbriatus* (Goldfuss). The new rotifer has the following specific characters; the corona is quadrate in plan and its base not wider than the body, with a flattened truncate lobe at each angle and a prominent lip on the ventral edge. There is no dorsal lobe, there are long cilia on the lobes, and on the dorsal and lateral rims of the corona is an inner series of short inactive cilia and an outer series of cilia in constant flagellatory motion. The long foot is frequently four times, or even more, the length of the corona and trunk combined. Wright proposes the name *Collotheca quadrinodosa* n. sp.

The Brandberg and Other Rock-Shelter Paintings of the Union of South Africa

THE Abbé Breuil's contention that the Brandberg paintings were of vast antiquity and the so-called 'white lady' a portrait of a European has been hotly contested by prehistorians in South Africa. Some years ago the late Dr. van Riet Lowe suggested that the date could equally well be A.D. 1600 or 1600 B.C. Indeed, nowadays, it is becoming more and more difficult to assign any great age to the rock-shelter paintings in the sub-continent. Revel Mason further points out that though some of the painted individuals seem to show Caucasoid features, such features are common among the southern Bantu to-day. Again, the smearing of white paint on the face for certain ceremonial purposes is not unknown. The physical characters shown in the Tsisab paintings, therefore, give no very certain evidence as to racial type, but the clothing, ornaments, etc., depicted fit in with those found among primitive tribes south of the Zambesi. There is no need to suggest relationship with Cretan or Egyptian originals, or to advocate any very great antiquity for this art. Revel Mason is well known among the younger prehistorians in South Africa. Under the auspices of the Archæological Survey of the Union of South Africa, Pretoria, he has published a pamphlet full of coloured illustrations dealing with his discoveries of a new series of rock-shelter paintings in the Brandberg, south-west Africa and another series at Waterberg, Northern Transvaal. While the whole is only a few pages in length, it is an attractive little work which adds to our knowledge of South African rock-shelter art.

Scientists Working in Antarctica

THE Special Committee on Antarctic Research of the International Council of Scientific Unions now maintains a register of scientists wishing to work on Antarctic expeditions of other nations. The Committee is merely acting as a centre which may put suitable scientists from other countries in touch with national committees which can use their services to advantage. Further arrangements for the employment of individuals are then a matter of negotiation between the expedition organization and the person concerned. Men with previous polar experience would be most suitable. Registration forms are available from the Assistant Secretary, Royal Society, Burlington House, London. W.1.

Ford Foundation Grant to the Zoological Society of London

THE Zoological Society of London has received a further grant of 95,000 dollars from the Ford Foundation to supplement the grant of 550,000 dollars announced in May 1960. Both these grants have been made to support a programme of research in animal reproduction. The original grant of 550,000 dollars from the Ford Foundation was to endow a series of research fellowships, and the appointments of Dr. Peter Jewell, Dr. Lorna Kellas and Mr. David Kirby to the first three fellowships were announced in February of this year.

Royal Geographical Society Award for Women

As the result of a bequest from the late Lady Dorothy Mills, Fellow of the Royal Geographical Society, an award of £1,000 has been established, to be known as the Lady Dorothy Mills Award. The Award will take the form of a studentship involving some element of adventurous travel or exploration, by land or air, tenable for one or more years within the limits of the sum available. Applicants (of any nationality) must be women over twenty-one and preferably under the age of thirty years. They must be Fellows of the Royal Geographical Society. The study which forms part of the candidate's programme may be in any field of science or the humanities, provided that it has some geographical content or aspect. Further information can be obtained from the Director and Secretary, Royal Geographical Society, 1 Kensington Gore, London, S.W.7. Applications must be submitted by February 12, 1962.

International School for Research and Education in Physics

AN international school for research and education in physics has been established at the University of Uppsala. The school is being jointly sponsored by the International Atomic Energy Agency, the United Nations Educational, Scientific and Cultural Organization and the Central Committee for Swedish Technical Assistance. The school is offering one-year courses, the first of which will start on September 1 and finish about July 1, 1962. The aim of the school is to provide possibilities for individual participation in qualified experimental research work in one of the various fields of physics under experienced guidance. The school is open to participants from all countries and a number of fellowships will be available. Further information can be obtained from the International Seminar, Institute of Physics, University of Uppsala, Uppsala, Sweden.

National Agricultural Advisory Service

RECENT changes in the National Agricultural Advisory Service include the following: Mr. J. Butt-Evans, at present county advisory officer for Durham, to be county advisory officer for Yorkshire (North Riding), in succession to Mr. W. S. Rayfield, who was recently transferred to headquarters; Mr. G. P. Chater, at present hops adviser in the West Midland Region, to be director of the Rosemaund Experimental Husbandry Farm, Preston Wynne, Hereford, in succession to Mr. E. L. Jones, who succeeds Mr. W. R. Smith as one of the two livestock husbandry officers for Wales.

American Geophysical Union : Officers

THE triennial elections of the national officers of the American Geophysical Union have recently been held, and the following have been elected for a three-year period from July 1: *President*, Dr. Thomas F. Malone, director of research, Travelers Insurance Co., Hartford, Connecticut; *Vice-president*, Dr. George P. Woollard, professor of geophysics, Department of Geology, University of Wisconsin; *General Secretary*, Dr. A. Nelson Sayre, senior scientist, U.S. Geological Survey, Washington, D.C.

The Night Sky in May

NEW moon occurs on May 14d. 16h. 55m. U.T. and full moon on May 30d. 04h. 38m. The following conjunctions with the Moon take place: May 6d. 12h., Saturn 3° S.; May 7d. 00h., Jupiter 3° S.; May 11d. 16h., Venus 4° N.; May 20d. 18h., Mars 4° N.; May 22d. 13h., Regulus 0·7° N. In addition to these conjunctions with the Moon, Mercury is in conjunction with Aldebaran on May 15d. 22h., Mercury being 7° N. Mercury is an evening star, and is visible in the west after sunset; on May 31 it sets about two hours after the Sun. Venus is a morning star, but it is too close to the Sun for easy observation. Mars is an evening star, but conditions for observation are becoming less favourable. It sets about midnight; its stellar magnitude is + 1·5 on May 15, and its distance from the Earth on May 15 is 158 million miles. Jupiter rises at 1h. 40m., 0h. 50m. and 23h. 45m. on May 1, 15 and 31, respectively. It is in Capricornus, its stellar magnitude on May 15 is – 2·0 and its distance from the Earth on that date is 440 million miles. Saturn rises at 1h. 20m., 0h. 45m. and 23h. 20m. at the beginning, middle and end of the month, respectively. It is near the border of Sagittarius and Capricornus; on May 15 its stellar magnitude is + 0·7 and its distance from the Earth is 890 million miles. There is one occultation of a star brighter than magnitude 6 visible at Greenwich; May 2d. 23h. 16·6m., 24 Sco., reappearance.

Announcements

Prof. Jean Brachet (Brussels) and Prof. Hans Bauer (Wilhelmshaven) have been awarded the Schleiden Medal of the Leopoldina German Academy of Science, for their outstanding work in the field of cytology.

DR. B. P. PAL, director of the Indian Agricultural Research Institute, New Delhi, has been awarded the first Rafi Ahmed Kidwai Memorial Prize of the Indian Council of Agricultural Research, for his work on the breeding of Pusa wheat varieties.

Mr. E. S. Calvert and Mr. J. W. Sparke, both of the Ministry of Aviation's Royal Aircraft Establishment, Farnborough, have been awarded the 1961 Laura Taber Barbour Air Safety Award, in recognition of their "major contribution to world air safety through joint development of the Line and Bar Approach Lighting System and the Visual Glide Path Indicator now installed and in use at many major airports". The Award is made annually by Flight Safety Foundation Award Inc., of the U.S. Society of Automotive Engineers Inc.

THE Duke of Edinburgh will open the McFadzean Laboratory at the Wood Lane research centre of British Insulated Callender's Cables, Ltd., on May 16.

THE Bradford Institute of Technology is organizing a special short course on "Methods of Polymer Characterization and Analysis" during June 23–24. Further information can be obtained from the Registrar, Institute of Technology, Bradford 7.

THE Biology Department of Brookhaven National Laboratory is organizing a symposium on "Fundamental Aspects of Radiosensitivity" during June 5–7. Further information can be obtained from Dr. A. H. Sparrow, Brookhaven National Laboratory, Associated Universities Inc., Upton, L.I., N.Y.

THE Applied Spectroscopy Group and the Manchester and District Branch of the Institute of Physics and the Physical Society are holding a joint one-day meeting on "Spectroscopic Studies using Time Resolution Techniques", on June 16. Further information can be obtained from the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE International Academy of Astronautics of the International Astronautical Federation is organizing a symposium on "Space Flight and Re-entry Trajectories" to be held in Paris during June 19–21. A number of symposia are planned, dealing with the following subjects: trajectories for lunar and interplanetary missions; orbital transfer and rendezvous; near-Earth satellites; dynamics of terminal re-entry. Further information can be obtained from the International Academy of Astronautics, 12 Rue de Gramont, Paris 2e.

THE British Biophysical Society is organizing a meeting at the University of Nottingham during July 26–28. Two symposia are being organized: "Phloem Transport in Plants" and "Electron Transfer in Biological Molecules". There will also be a session for the reading of papers, and a discussion on "International Organization in Biophysics". Further information and application forms can be obtained from the honorary treasurer, Dr. P. M. B. Walker, Zoology Department, University of Edinburgh, West Mains Road, Edinburgh.

AN informal meeting is to be held at the Royal College of Science and Technology, Glasgow, on June 27, under the auspices of the Faraday Society, to mark the centenary of the publication by Thomas Graham of his paper on liquid diffusion, in which he distinguished between colloids and crystalloids. Mr. D. C. Henry, of Manchester, will preside, and speakers will include: Sir Eric Rideal, Prof. J. A. V. Butler, Dr. A. S. C. Lawrence and Dr. A. P. Prosser. Further information may be obtained from Dr. A. J. Hyde, Department of Chemistry, Royal College of Science and Technology, George Street, Glasgow, C.1.

THE BELGIAN ADVISORY COUNCIL FOR SCIENTIFIC POLICY

THE Belgian Advisory Council for Scientific Policy was established by a royal decree of September 16, 1959, which also established a Ministerial Committee of Scientific Policy and an Inter-departmental Commission of officials. The Council, of which Prof. L. Massart is chairman and Prof. M. Dubuisson vice-chairman, is to study, in close co-operation with the universities and equivalent institutions of higher education, the development of these institutes commensurately with the nation's needs and make appropriate proposals, as well as the extension of research; to maintain records of the nation's research services and their work; to propose ways of promoting and co-ordinating scientific research in both the economic and the academic sector; to formulate an overall programme for the expansion of research, and to suggest appropriate means of financing scientific research; to study conditions determining efficiency in research and methods of co-ordinating the application of results; and to advise the Government on Belgian participation in international scientific activities. The Council is assisted by two standing committees, an Industry–University Liaison Committee and a Committee of Scientific Experts, and it has already established working parties on medical research and agronomic research.

The Council's first annual report covers the period September 1959–September 1960, in which the broad lines of an overall programme are first outlined, while in the second part of the report the Council's operations are surveyed and in particular the recommendations it has already made (Pp. 132. Bruxelles: Conseil National de la Politique Scientifique, 1960). The first aim of scientific policy is seen as the development of scientific research and the training of man-power for this purpose, and it is the task of the Council to define with sufficient accuracy the objectives of scientific policy and the means to be used to achieve them in the light of economic policy and resources. This involves the submission of recommendations regarding man-power, institutions and resources, and the report considers in some detail the adaptation of the equipment of Belgian universities to the new needs arising in university expansion and the adaptation of methods of teaching and training.

The Council is particularly concerned about the problems of a reasonable balance between the numbers of young people trained for particular occupations and the number of appropriate openings. As regards institutions, the Council has already endorsed the findings of the National Science Commission, which proposed a five-year plan for expanding the universities' scientific, technological and administrative man-power, higher subsidies for the non-State universities and a plan for expanding the State universities. Certain fundamental reforms in university curricula are put forward as urgent, and a University–National Council Liaison Committee has been established. The Council has also urged recommended implementation of plans recently drafted for expanding the staff of scientific establishments under the Ministry of Education. With regard to finance of scientific research, the Council has recommended the appropriation of 75 million francs, to be allocated progressively during 1961 to new projects as they appear desirable.

Discussing international aspects of scientific policy, the report stresses the importance and efficacy of international co-operation in research, as in the European Nuclear Research Centre, and particularly its value to the smaller countries. Finally, the problem of scientific institutions in the Congo is briefly discussed.

THE WOOL INDUSTRIES RESEARCH ASSOCIATION

NEW LABORATORIES FOR WORSTED PROCESSING

THE new Worsted Processing Block at Torridon, the Leeds headquarters of the Wool Industries Research Association, was opened by the Right Hon. R. G. Menzies, Prime Minister of Australia, on March 22.

Both the chairman of the Association, Mr. Basil A. Smith, and the director of research, Dr. A. B. D. Cassie, have long been concerned with the development of worsted processing research at Torridon. Mr. Smith has been very active in the Association's affairs since 1929, particularly in the field of scouring and combing, and also in that of finance—an important aspect when new projects are planned. Dr. Cassie joined the staff of the Association in 1938 as head of the Physics Department and was appointed director of research in 1950. Much of his own work has been of direct and indirect importance to the worsted industry; for example, his researches on the flow of air through porous plugs led to the development of the Association's fibre fineness meter, now widely used in the industry.

Early Researches

The programme of work being undertaken in the new laboratories inevitably stems from earlier fundamental and applied researches relative to the processes concerned: scouring and drying of loose wool, carding, combing, drawing and spinning. In 1920 very little was known about the physical properties of the wool fibre. The general principles of the exchange of moisture between wool and the ambient atmosphere were understood; and there were methods for measuring the moisture content of wool. But virtually nothing was known about the effect of the moisture content of wool at the various stages of processing, how it changes during processing, and how the moisture content is affected by the relative humidity of the atmosphere. These subjects have been thoroughly investigated, and the findings are now applied in the industry. The first testing room with controlled atmosphere was set up at Torridon; the method used, that of wetting

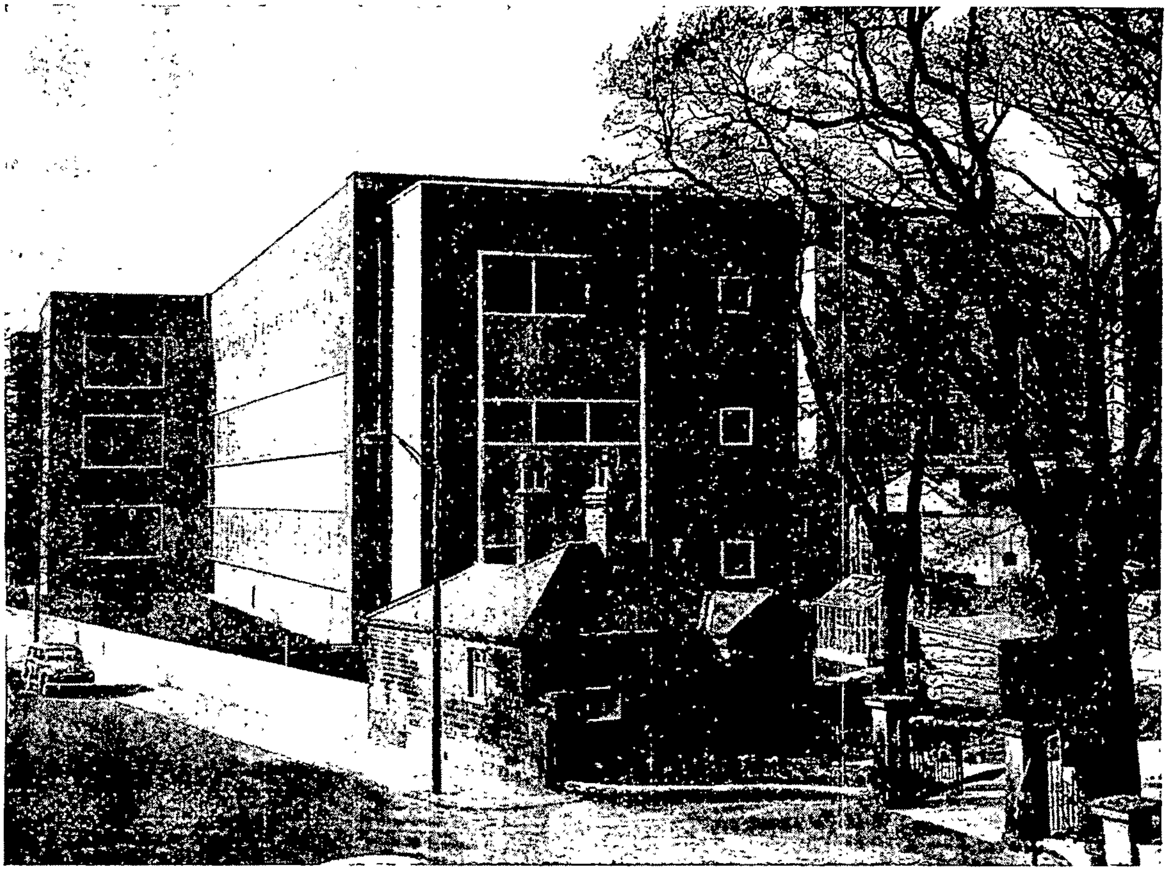

Fig. 1. The new Worsted Processing Block at Torridon, Leeds

and drying towers, was later adapted for commercial control cabinets.

Before 1920, although the industry used several methods for combating the effects of static electricity, little was known about its cause. This phenomenon was studied, therefore, and the findings indicated that the most effective way of dealing with 'static' is to attack it at its source. This knowledge has been used by chemical manufacturers in the development of anti-static dressings for use on wool during processing.

Scouring

The change of *p*H in the liquors during scouring, the use of various alkalis, and the scouring properties of suint (exudation from sweat glands of the sheep) have all been investigated at Torridon since the early 'thirties. In 1953 a complete scouring plant was installed and has now been transferred to the new Worsted Block. Recent research work has led to a greater understanding of the physico-chemical mechanism of scouring, and of the mechanical action. It has been shown that most of the mechanical scouring action takes place not in the bowls but at the point where the liquor is expressed by the squeeze rollers. This type of research has involved the devising of methods for separating and measuring the constituents of the liquors: grease, soap and free fatty acids.

Carding and Combing

The avoidance of fibre breakage is an important requirement in the early stages of worsted yarn production. Investigations have shown that fibre breakage in worsted carding depends largely on the state of the wool coming from the scouring. This finding has stressed the desirability of a gentle mechanical action in scouring. The modern type of air-flow dryer through which the wool passes after scouring, using the principles advanced by the Wool Industries Research Association in 1938, also does much to lessen the entanglement of the fibres.

Progress in methods for the removal of burr (vegetable matter) in carding had at one time been hampered by the difficulty of estimating the amount of burr in a sample. Satisfactory mechanical and complementary chemical methods of estimation have now been developed and the requirements for efficient burr removal are consequently more thoroughly understood.

Research in combing is being directed to the improvement in the thickness regularity of the combed sliver, this having increased in importance with the introduction of the new drawing and spinning techniques mentioned here.

Drawing and Spinning

About eight or ten stages of attenuation had been traditionally used in drawing 'tops' (the product of the comb) to the 'roving' from which the worsted yarn is spun. The development of the Association's roving levelness tester and the early work on roving and yarn irregularity led to the introduction of shorter processes by many firms. An outcome of this line of advance was the invention of the Raper autoleveller, a drawing machine which maintains thickness regularity by automatically taking account of the irregularity of the ingoing material. Mr. George Raper brought his idea to Torridon for early development, and after further development in a mill it was put into commercial production. This system of drawing, in conjunction with the Ambler 'superdraft' system of spinning (developed by Mr. Geoffrey Ambler with the co-operation of the University of Leeds), is now accepted as one of the modern methods of worsted drawing and spinning.

A more recent achievement, used as a part of a shortened drawing system, is the Association's rotating can system, in which twist is inserted by means of a rotating can instead of a spindle. Other investigations in improved methods of worsted drawing are being pursued at Torridon, including the use of closed loop servo-techniques for autolevelling.

An important aspect of the irregularity of the ultimate yarn is its effect on the appearance of the fabric. The Association has pioneered the expression of this irregularity in numerical form, and the problem of linking numerical assessment with visual judgment is still being studied.

Many other projects are in hand, both in scouring and combing and in drawing and spinning. Members' day-to-day problems often lead to some profitable line of research the solution of which benefits the industry as a whole. The use of man-made fibres in blends with wool raises difficulties at various stages of processing. New types of machinery introduce new aspects of old ones. This kind of service to the industry will be greatly facilitated by the increase of machinery and laboratory space in the new Worsted Block.

H. Lemon

APPLICATIONS OF INTERFERENCE MICROSCOPY

A SYMPOSIUM on this subject was held at the Royal Microscopical Society's London headquarters on March 15. The president, Dr. V. E. Cosslett, was in the chair and the audience included a number of visitors from abroad. It is nearly ten years since the first interference microscopes suitable for general use began to appear, and the purpose of the meeting was to take stock of the present position and to review some of the main applications of the instrument in various fields.

In his introductory survey Dr. R. Barer (Oxford) dealt with the instrument, theory of operation and the principles underlying its use for 'weighing' cells. He paid tribute to the work of J. Dyson, F. H. Smith and J. St. L. Philpot, who made the development of modern high-aperture instruments possible, and discussed some of the problems common to all types of interference microscope. The operation of a two-beam interference microscope can be explained by means of a simple vector theory which shows how the optical path difference produced by a transparent specimen can be measured and also demonstrates the similarity between interference and phase-contrast microscopy. The latter can be regarded as a form of interference microscopy in which the two interfering beams are imperfectly separated. This causes the edge of a refractile object to be surrounded by a halo and the contrast of edges and discontinuities is accentuated. These apparent defects of phase contrast are not necessarily a disadvantage for purely observational work; and the image of a cell seen through an interference microscope is often disappointingly 'flat' and lacking in internal contrast as compared with a phase-contrast image. Dr. Barer concluded by giving a practical interpretation of the meaning of optical path difference, the quantity normally measured with an interference microscope. The refractive index of a solution varies linearly with its concentration and since the optical path difference is defined as the product of the object thickness and the difference in refractive index between the object and the surrounding medium, it follows that the optical path difference is proportional to the dry mass per unit area. This is an important quantity in cytology, but present methods are mainly adapted to point-by-point measurements and the integration of dry mass over the area of a cell might be very tedious. The full value of interference microscopy in biology will not be realized until automatic integrating devices, based on rapid electronic scanning and capable of 'weighing' a cell in a fraction of a second, have been developed. This is a technical problem and by no means insoluble.

Dr. K. F. A. Ross (Leyden) described how interference microscopy can be used to measure the mass or solid concentration of cell inclusions. It is necessary to overcome the difficulty that the inclusion is surrounded by a layer of cytoplasm of unknown thickness. One method is to immerse the cell in an isotonic protein solution having the same refractive index as the cytoplasm. The difference in refractive index or concentration between the inclusion and the cytoplasm can then be found. Measurements of this type have been made on the Nebenkern of the locust spermatid, a body formed by the fusion of mitochondria. Values in the range of 21–26 per cent for solid concentration were obtained. Work on lipid droplets in various cells has thrown some light on their physical state. The refractive index of droplets known to contain mainly phospholipids is considerably lower (about 1·42) than that of any pure lipid substance. This suggests that in their natural state these bodies are highly hydrated, a conclusion supported by evidence from polarization and electron microscopy. Finally, Dr. Ross described measurements on different regions of the giant salivary gland chromosomes of *Chironomus*. A number of different methods all showed that the euchromatic regions contained a higher concentration of solids (20–25 per cent) than the heterochromatic regions (10–15 per cent).

Dr. E. J. Ambrose (London) described his work on cell division. The instrument used was a polarizing type of interference microscope with a birefringent wedge mounted in the eyepiece. Time-lapse ciné-films in colour were taken of dividing cells, simultaneously with a coloured image of the wedge. The optical path difference of any part of the cell could be measured by matching its colour against the scale of colours exhibited by the wedge. In some cases it was necessary to compress the cells in order to obtain good optical conditions, but with plant endosperm the cells could be mounted on a thin film of agar on which they were made to spread out by surface tension. Measurements were made on the cytoplasm, nuclear sap, chromosomes, spindle and cell plate. A good correlation was found between regions of high mass per unit area and the development of birefringence. Dr. Ambrose concluded by showing some excellent colour films of cell division.

The three papers in the afternoon session were devoted to non-biological applications. Dr. S. Goldstaub (Strasbourg) first described his work on crystal growth. The interference fringes surrounding a crystal immersed in its mother liquor are in fact lines of equal concentration. In regular growth these fringes tend to cut across the corners of the crystal, so that the crystal surface is not a region of constant concentration. Nevertheless, since the fringes move parallel to themselves during growth, an equal mass of material is deposited over the whole surface. In dendritic growth, on the other hand, the fringes do not cut the crystal surface. Dr. Goldstaub also gave an interesting account of the use of the interference microscope for studying the behaviour of salt solutions surrounding isolated particles of ion exchange resins. The flow of ions from the solution to the resin gives rise to concentration gradients, and hence to fringes around the particles so that the exchange process can be observed directly. A colour film illustrating some of these points was shown.

Dr. R. C. Faust (Imperial Chemical Industries, Ltd., Northwich) discussed the study of optically heterogeneous specimens with special reference to textile fibres. Many fibres are far from homogeneous and some possess a surface layer or 'skin' that differs markedly from the central core. A knowledge of the absolute refractive indices at different parts of a fibre is an important guide to the degree of molecular packing and orientation. A convenient method of observing the variation in refractive index is to immerse the fibre in a liquid of known refractive index and to study the way in which interference fringes are deviated in traversing the image of the fibre. At those points at which the fringe is undeviated the refractive index of the fibre matches that of the liquid. If the refractive index of the liquid is changed by varying the wave-length or the temperature, new match positions are obtained. A map of refractive index variation can thus be built up. In some unstretched fibres the refractive index for polarized light vibrating parallel to the axis remains essentially constant across the fibre whereas for light vibrating perpendicular to the axis the index falls rapidly from the edge to the centre, so that the birefringence is maximal at the edge. After stretching, however, both refractive indices vary together, giving uniform birefringence. Dr. Faust emphasized that the optical properties of fibres vary considerably, depending on the method of manufacture.

A glimpse into the future was provided by the last speaker, M. Marcel Locquin (Paris). He described how microscopes are needed to magnify the very small 'memories' used in machines for automatic documentation and translation. The 'memories' are produced as photomechanical negatives by a process similar to that used for making graticules. Although in most European languages 40,000 phrases are in common use, about 90 per cent of a language can be translated with only 2,000–4,000 phrases. A common word can be represented by one or more letters using speedwriting shorthand. Additional letters are used to represent the dependence of one word on another. The encoded phrases are made into a memory which can be a thousand times smaller than a magnetic type of memory. The memory negative is magnified through a microscope and its enlarged image falls on to a 'question' in the form of a photographic positive. A photoelectric system measures the amount of light transmitted by the overlapping images; if the memory and the question are identical no light is transmitted and various degrees of similarity can be selected according to the light transmitted. Such a system can be used for selecting papers on similar subjects without human intervention. The particular advantages of an interference microscope for this work are that it provides a means of contrast variation and that silver grains in the photographic emulsion are rendered essentially transparent by interference contrast, so that the image is effectively grain-free. However, M. Locquin felt that there were possibilities for reducing the size of the memories still further and looked forward to the day when they would have to be magnified by means of an electron microscope.

R. BARER

THE CARNEGIE TRUST FOR THE UNIVERSITIES OF SCOTLAND

THE fifty-ninth annual report of the Carnegie Trust for the Universities of Scotland, covering the year 1959–60, includes that of the Executive Committee, the abstract of financial accounts for the year ended September 30, 1960, lists of publications during the year from Fellows, Scholars and recipients of grants, and of papers published by the Royal Society of Edinburgh assisted by Carnegie grants, and the usual reports on the work of Fellows and Scholars and on research grants and travel grants awarded during the year*.

In annual and non-recurrent grants in the 1957–62 quinquennial distribution the heaviest items have been more than £18,000 by St. Andrews on the new Biology building, a similar sum by Glasgow on the new Arts building, and more than £23,000 on the new Physical Education Centre ; more than £26,000 by Aberdeen on the new hall of residence, Crombie Hall, and nearly £9,000 by Edinburgh on the new hall of residence at Salisbury Green (Holland House). The Committee is now considering its policy with regard to capital grants for the period 1962–67, and has agreed to ask each university, in formulating proposals for use of the Trust's funds in this eleventh quinquennial distribution, to concentrate on projects which are not supported by the University Grants Committee.

---

* The Carnegie Trust for the Universities of Scotland. Fifty-ninth Annual Report for the year 1959–60 submitted by the Executive Committee to the Trustees on 27th February, 1961. Pp. iv+66. (Edinburgh: Carnegie Trust for the Universities of Scotland, 1961.)

Expenditure on the research scheme has risen to more than £117,000, that on postgraduate scholarships and fellowships remaining about the same. During 1959–60 all four Fellows were in the humanities, but 3 out of 5 Senior Scholars and 31 out of 56 Scholars were in science; 19 Scholars, 3 Senior Scholars and 3 Fellows were new appointments. Of 44 research grants, 13 were towards the cost of illustrating research papers with special diagrams, maps or photographs, and 10 were travel grants of special kinds. Seven major travel awards were made, making a total of 40 over the past three years, and the Committee continues to attach great importance to these foreign travel awards. The policy remains clear-cut: a high standard of research achievement must be established; the journey proposed must be based on the intention to carry out research or acquire new research techniques; and no applications will be accepted where the central purpose is to attend an international conference. Awards in 1959–60 include those to E. W. Fisher for comparative studies of the cardiovascular system of the horse, cow and dog, at Pennsylvania; G. F. Hamilton, for studies of the supplementary motor areas of the primate cortex at Michigan; G. Eglinton, to study chemical constituents of the flora of the Canary Islands; N. A. Mitchison, to study cellular aspects of antibody synthesis at Stanford; and R. G. Moorhouse to study elementary particle physics at the European Centre for Nuclear Research, Geneva.

Only seven authors received subventions towards the cost of publishing books, and while the policy of aid for the Scottish learned societies with the cost of publishing their *Proceedings* or *Transactions* continued, the Committee intends to adhere strictly to its new policy of reviewing applications simultaneously once a year, and imposing a ceiling of £2,500 on such expenditure.

NATURE OF SARCOLEMMA, THE STRIATED MUSCLE FIBRE MEMBRANE

By Prof. F. LŐRINCZ and Dr. G. BIRÓ

Hungarian Meat Research Institute, Budapest 2

THERE is a close relationship between the structure of muscle tissue and the palatability of meat, above all, its softness, tenderness, and even its biological value (for example, the ratio of true muscle tissue to connective tissue). Among the tissue components of the muscle cells, the structure and function of the sarcolemma have not yet been examined in such detail as those of other components of the muscle cells.

Jones and Barer[1], Rózsa, Szent-Györgyi and Wickoff[2], Conte and Rieser[3] and Wang[4] have investigated the nature of sarcolemma. Jones and Barer failed to confirm the opinion that the sarcolemma is a sheath composed of fine collagenous or reticular fibrils. By means of the electron microscope it was recognized as a fine membrane on which small spots were seen. According to these authors, it is possible that the small spots might be points of attachment of either connective tissue fibrils or myofibrils. Rózsa *et al.* described the sarcolemma as a thin sheet having a granular surface to which threads are attached. According to their view, these threads actually do not belong to the sarcolemma, but rather to the system of fibrils surrounding the muscle fibres. After a critical survey of the assertions of other authors, Conte and Rieser suggested, as a result of their tests, that the sarcolemma is a protein membrane free of a collagenous or fibrillar structure. It is most likely a lipoprotein, and this is in agreement with the fact that also the mammalian erythrocyte envelope is a membrane of this type. Finally, according to Wang's view, the bipartite nature of the sarcolemma can be recognized. The true sarcolemma is a homogeneous membrane about 0·1μ thick, which is surrounded by the fibrous sarcolemmous envelope.

We have also examined the finer structural conditions of muscle, from both chemical and histological points of view[5,6]. For our experiments reported here, we took samples from the gluteus medius of a cow about 3 years old, a quarter of an hour after death. After having freed the samples carefully from the other visible tissue elements, that is, the adipose and coarse components of the connective tissue, the samples were transversely cut up into small pieces measuring about 3–5 mm. in thickness and disintegrated in sterile physiological solution of sodium chloride utilizing a Waring blender. Our purpose was to obtain isolated muscle fibrils.

On examining the disintegrated tissue under a microscope, a phenomenon formerly not experienced

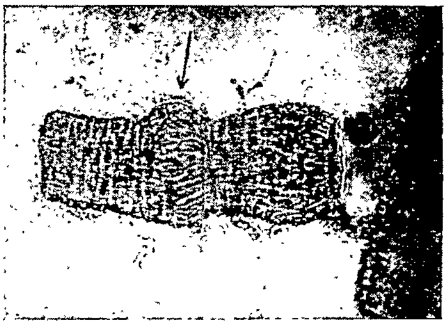

Fig. 1. (× 200)

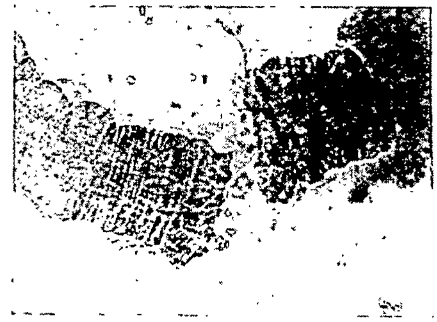

Fig. 2. (× 200)

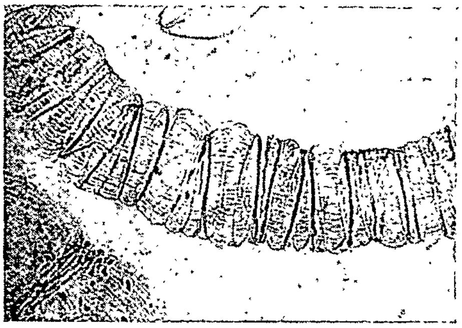

Fig. 3. (× 200)

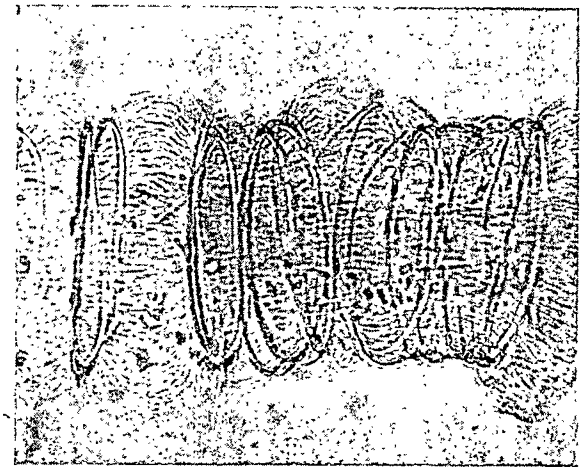

Fig. 4. (× 500)

was seen (Figs. 1–4). The majority of the muscle cells were separated into fibril fragments. However, rather short muscle cell parts which were surrounded by a more refractive connective tissue structure, exceeding in thickness the fibrils and resembling a spiral rim, could be seen. This structure, composed of circular fibres, was interrupted in many places, due to treatment in the homogenizer. As a matter of consequence, the originally presumably regular and dense 'winding' became not only loose but also the fibril bundles, freed from the elastic hold, were also—so to speak—escaping from the tight connective tissue grasp. As the loosened, here and there, ruptured circular fibres slipped towards one another, the fibril bundles appeared between them like a hernia.

Fig. 1 shows a relatively intact muscle cell. At one spot, however, the fibrils are already protruding under the connective tissue 'wire', holding together still concentrically and rather regularly. In Fig. 2 the 'winding' has been damaged more severely, and this phenomenon is still more apparent in Figs. 3 and 4.

In order to clarify the nature of the fibre structure holding together the muscle cells, the muscle tissue disintegrated in the homogenizer was held for 24 hr. at room temperature in 0·2 *N* sodium hydroxide solution, then, after washing in water, placed in hot 0·66 per cent solution of tartaric acid for 30 min. The purpose of this treatment was to remove the muscle protein and the collagen. Fig. 5 illustrates a preparation treated in such a way, on which the faint design of the fibre structure showing the outline of the muscle cell can be recognized. This test seems to verify the collagenous fibrous nature of the structure. This might be the exterior fibrous envelope surrounding the homogeneous membrane of true sarcolemma, as described by Wang.

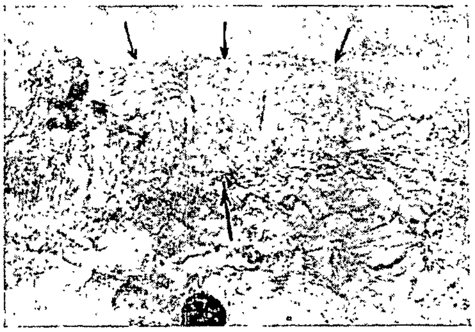

Fig. 5. A fragment of muscle fibre, treated in 0·2 *N* sodium hydroxide solution and then in hot 0·6 per cent tartaric acid solution (arrows). The concentric fibres have disappeared and only their traces can be detected. (× 250)

Fig. 5 presents some fine undulating elastic fibres which presumably belong to the endomysial connective tissue.

UBIQUINONE (COENZYME Q) AND THE FUNCTION OF VITAMIN E

By Dr. J. GREEN, A. T. DIPLOCK, J. BUNYAN, Dr. E. E. EDWIN and Dr. D. McHALE

Walton Oaks Experimental Station, Vitamins, Ltd., Tadworth, Surrey

VITAMIN E comprises a small group of closely related substances, the most important of which is α-tocopherol. α-Tocopherol is widely distributed in the plant kingdom, has been found in unicellular organisms[1], yeasts and fungi[2], and, so far as we are aware, occurs in all animal tissues. It can be readily observed in even the most carefully prepared 'vitamin E-free' diets[3] based on natural foodstuffs and also in all the tissues of animals reared on such diets, provided that suitable analytical procedures are used. All though it appears likely that vitamin E is a normal constituent of most living things, little is known of its biochemical role, and nutritional vitamin E-deficiency in animals is characterized by a great variety of clinical, physiological and histopathological symptoms, the very diversity of which has usually proved more of an embarrassment than a help in attempts to understand the fundamental processes involved in the deficiency state. Thus chicks may exhibit three different vitamin E-deficiency syndromes (muscular degeneration, exudative diathesis or encephalomalacia), separately or together, depending on the composition of their diet. Some species, such as the rat, are affected by failures in reproduction due to a variety of causes; other species, such as the pig, suffer hepatic disorders; still other species are subject to diseases chiefly affecting vascular or adipose tissue.

It is essential for an understanding of the role of vitamin E that these diverse manifestations produced by the same deficiency should be correlated with function, and we have already made the suggestion that animal tissues can suffer local and specific tocopherol deficiencies that may account for the nature of the syndrome in any given species[3,4].

A great advance was made, if not in our understanding, at least in our appreciation of the complexities of the vitamin E problem, when Schwarz and Foltz[5] discovered that selenium was able, like α-tocopherol, to prevent nutritional hepatic necrosis in the rat. Since then, many other workers have demonstrated that selenium and α-tocopherol have similar physiological effects in preventing some, but by no means all, of the symptoms of deficiency in a variety of animal species, and it is now certain that a fuller comprehension of the function of vitamin E must include an understanding of the role of selenium, both with regard to their similarities and even more to their interesting differences. It seems reasonably clear that at least three types of deficiency state can be discerned in animals: (1) diseases such as the hepatic necroses of the rat, mouse and pig, and the exudative diathesis of chicks, which can be prevented with either tocopherol or selenium, partially or totally; (2) at least some, and possibly all, disorders of reproduction and fertility (as in the rat, chick, and turkey) as well as encephalomalacia in the chick and muscular dystrophy in the rabbit, which can only be prevented with tocopherol; (3) muscular degenerations in species such as the sheep, which may be primarily due to selenium deficiency, although they can be either prevented or ameliorated by tocopherol. To these three conditions (and there are no doubt other intermediate states still to be elucidated) may perhaps be added a further category, namely, diseases of adipose tissue, such as the 'yellow fat' diseases of the cat and mink, in which only tocopherol appears to play a part. Formally the latter may fall within the realm of category (2) above, but because of the unusually clear effects on lipid metabolism in diseases affecting adipose tissue, they may with advantage be separated at present.

Active Metabolite of α-Tocopherol

In this article we wish to examine in further detail the nature of the function of α-tocopherol in animals and present some new evidence concerning its biochemical role. We have shown previously[3,4] that deficiencies of tocopherol and selenium in the rat and the rabbit produce a decrease in tissue levels of ubiquinone (coenzyme *Q*). It was also shown that dietary supplementation or oral dosage with either substance produced marked increases in ubiquinone concentrations in these animals (these effects can also be produced in avian species—to be discussed elsewhere), and we have already discussed[3] some possible connexions between these observations and the physiological effects of vitamin E in animals. In these earlier experiments our general technique was to give doses of α-tocopherol to deficient animals and kill them after 72 hr., after which time ubiquinone was measured in their tissues by methods described previously[6]. Table 1 gives the results of an experiment in which rats were given intravenous injections of 500 μgm. of α-tocopherol and examined after 2 hr. The technique in this and in similar experiments described afterwards was as follows: The animals in each test, randomized into appropriate groups, were anæsthetized lightly with ether. Tocopherol (emulsified in normal saline, containing 'Tween 80') was administered intrajugularly, and the wound was then closed with a clip and the animals allowed to recover. The operation generally took only a few minutes, and during the remainder of the experiment the rats behaved normally. At the end of the appropriate test period the rats were killed. Pilot experiments showed that ether anæsthesia had no effect on ubiquinone-levels, except after prolonged and heavy administration (and then, usually, only in the kidney). In the experiment summarized in Table 1, marked increases in the ubiquinone-levels of heart, liver and kidney were produced 2 hours after injection with tocopherol and, most significantly, the increase that occurred in heart was observed before any increase in the tocopherol concentration in this organ could be detected. (In the Tables, the symbols UQ, UC and T have been used to signify ubiquinone, ubichromenol and tocopherol, respectively.) In subsequent experiments (not shown) the latter phenomenon could sometimes be observed in other tissues, depending on the dose administered and how soon afterwards the animals were killed. As a result of these experiments, it seemed possible that the effect on ubiquinone was produced not by tocopherol but by a metabolite—perhaps a water-soluble derivative—formed from it. Such metabolites are in fact known. Simon *et al.*[7] isolated two water-soluble degradation products of α-tocopherol from the urine of rabbits that had been given large oral doses of the vitamin. These two substances were shown to be 2-(3-hydroxy-3-methyl-5-carboxy)-pentyl-3,5,6-trimethylbenzoquinone (I) and the lactone (II) derived from it. Although these workers seem to have regarded the compounds at that time as excretory products, Mertz and Schwarz[8] showed them to be highly active, *in vitro*, in preventing the respiratory failure that occurs in liver slices taken from rats deficient in tocopherol and selenium, and Corwin and Schwarz[9] have recently found them to be as active as tocopherol in maintaining α-ketoglutarate oxidation in tocopherol-deficient liver homogenates. We obtained a generous supply of lactone (II) from Dr. J. Weichet of Prague

Table 1. EFFECT OF α-TOCOPHEROL ADMINISTERED INTRAJUGULARLY TO RATS

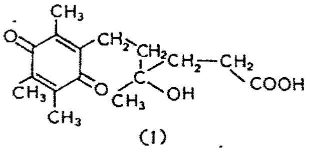
Group and treatment	Heart UQ	Heart UC	Heart T	Liver UQ	Liver UC	Liver T	Kidney UQ	Kidney UC	Kidney T
Controls	94	7	1·0	32	12	1·0	69	2	1·1
24 hr. after 1 mgm. tocopheronolactone orally	134	8	1·0	33	12	1·2	101	4	1·1
15 min. after 25 μgm. tocopheronolactone intravenously	166	18	1·3	50	19	1·0	81	4	1·3

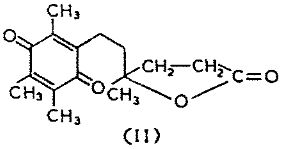
Three groups of six male rats, 9 months old, on diet *E*10*Y*. Results in μgm./gm. of tissue

(and later synthesized it in our laboratories) and examined it for its effect on ubiquinone in a number of experiments, some of which are summarized in Table 2.

It was found to be highly active, even more so than α-tocopherol itself when given in an equimolecular amount, either orally or when given intravenously. Marked increases in ubiquinone could be produced *within* 15 *min.* of injecting as little as 25 μgm. of lactone (II) intravenously into fully grown rats. In view of the likely physiological significance of these two metabolites, therefore, we propose that the name tocopheronic acid be given to compound (I) and that compound (II) be called tocopheronolactone.

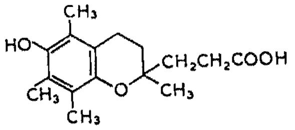


(I)



(II)

We have shown previously[10] that whereas α-tocopherol or selenium can control ubiquinone-levels in most tissues of the rat, only tocopherol is effective in the uterus, a phenomenon that is probably connected with the inability of selenium to prevent gestation-resorption. Since such important differences between tissues exist, it was clearly important to discover whether tocopheronolactone was as effective as α-tocopherol in the uterus and (for allied reasons) in the ovary. Table 3 gives the results of an experiment in which female rats were given oral doses of (*a*) sodium selenite, (*b*) α-tocopheryl acetate, or (*c*) tocopheronolactone, and killed 24 hr. later. Heart, ovary and uterus were analysed. Tocopheronolactone was found to be as active as α-tocopherol in all three tissues, and the experiment again confirmed the inactivity of selenium in uterus. Finally, Table 4 gives the results of an experiment that illustrates the differences in the rates of action of α-tocopherol and its metabolite. Rats were injected intrajugularly with small amounts of each substance (in equimolecular amounts). Groups of rats were killed both after 15 min. and after 120 min. and three tissues were examined in the usual way for effects on ubiquinone and ubichromenol. These were compared with tissues from negative and uninjected controls and also from groups of rats injected with bland saline 'Tween 80' solutions (used as vehicles for the tocopherol and tocopheronolactone). The results show that whereas after 15 min. the tocopherol was just beginning to take effect, the lactone was already fully active at this time in kidney and nearly so in heart and liver. After 2 hr. the effect of tocopherol was maximal, whereas the effect of tocopheronolactone in kidney was already on the wane, although it was still pronounced in heart and liver. An interesting feature of the analyses is that 150 μgm. of tocopherol was obviously insufficient to produce appreciable changes in the tocopherol-levels of the tissues: this quantity given to deficient animals can clearly be rapidly and practically completely metabolized during the 2-hr. period. In this experiment we also studied the effect of the interesting chromanol (III) (also prepared by Dr. Weichet), which is derived from tocopheronic acid. Although this substance was active in increasing ubiquinone in heart, it was quite ineffective in liver and kidney, where, indeed, ubiquinone-levels were actually depressed. These four experiments suggest that tocopheronic acid is either the physiologically active agent produced from tocopherol or that it is closely allied to such a derivative. We have had some indication that tocopheronolactone may itself be converted to another substance *in vivo*. Chromatograms of tissue extracts from rats given fairly large amounts of the lactone (1–2 mgm.) have shown the presence of a non-reducing lipid-soluble substance, chromatographically slower than α-tocopherylquinone in reversed-phase systems and therefore possibly of greater molecular weight, which spectroscopically appeared to be a typical



(III)

Table 3. EFFECT OF α-TOCOPHEROL, TOCOPHERONOLACTONE AND SELENIUM IN RAT HEART, OVARY AND UTERUS

Group and treatment	Heart UQ	Heart T	Ovary UQ	Ovary T	Uterus UQ	Uterus T

Chromanol (III)	30	137	N.D.*	1·8	18	11	0·5	50	19	2·8

Male rats (5 months old, on diet *E*10*Y*) were injected intrajugularly with α-tocopherol (150 μgm.) or tocopheronolactone (100 μgm.) or chromanol III (100 μgm.) dissolved or suspended in saline 'Tween 80' solution. Control rats were used with and without injections of bland saline/'Tween 80' solutions as two types of negative control. Results in μgm./gm. of tissue

* N.D., not detected.

substituted benzoquinone ($\lambda_{max.}$ at 259 and 268 mμ.), reducible with borohydride. Its significance is at present quite unknown.

Factors affecting Ubiquinone-levels in the Rat

It has become apparent from work with many groups of rats that tissue ubiquinone-levels in this species are subject to marked fluctuation, particularly in vitamin E-deficient animals but also in normal rats from the stock colony. Although the factors responsible are in the main unknown at present, one such factor is undoubtedly the nature of the diet, especially with regard to traces of vitamin E and selenium, but also with regard to gross composition. The diet (*E*10*Y*) used in our experiments contained very little tocopherol. Its composition was as follows: dried yeast (Marmite Food Extract Co.), 25; casein ('Genatosan', low vitamin content), 10 per cent; lard, 1 per cent; sucrose, 59 per cent; McCollum's salt mixture, 5 per cent; with the addition of 10 I.U. of vitamin A and 2·5 I.U. of vitamin D/gm. of diet. We have found that the use of this diet consistently produces low ubiquinone-levels in the rat, especially in liver. This can be seen from the results (Table 5) of an experiment that deals with another factor having a marked effect on ubiquinone-levels, namely, starvation. In this experiment, groups of rats on 3 diets were examined, in comparison with the controls, after being fasted for 18 hr. One group was fed diet *E*10*Y* for 6 months, the second group received the same diet supplemented with 100 mgm./kgm. of α-tocopheryl acetate, and the third group was on the adequate stock colony diet. Starvation increased ubiquinone markedly in the stock colony animals, less so in the other groups, but significantly in all livers. These observations are of especial interest since cholesterol synthesis is known to be markedly depressed in liver during fasting, and both the ubiquinone side-chain and cholesterol are derived from a common precursor, mevalonate. Bucher[11] has discussed some of the factors that might be concerned with the inhibition of cholesterol synthesis in fasted animals. Although these are far from clear, it appears that the process leads to a concurrent increase in ubiquinone (the amount of the latter in tissues being, of course, fairly small compared with the amounts of cholesterol). It should be noted that other factors have also been found to increase ubiquinone in the rat: these include uncoupling agents such as thyroxine and dinitrophenol[12] and substances that inhibit oxidation without uncoupling of phosphorylation[13], such as barbiturates (fuller details of this work will be presented elsewhere). In spite of the multiplicity of these effects, the possibility that they influence some common point in metabolism, of which the increase in ubiquinone may be only one aspect, must be considered.

Table 5. EFFECT OF STARVATION ON UBIQUINONE- AND UBICHROMENOL-LEVELS IN VITAMIN E-DEFICIENT AND ADEQUATELY FED RATS

Group	Treatment	Heart UQ	Heart UC	Heart T	Liver UQ	Liver UC	Liver T

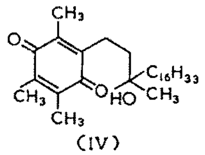
* N.D., not detected.

α-Tocopherylquinone

The discovery of physiological activity for tocopheronolactone inevitably raises anew the problem of α-tocopherylquinone. This substance (IV), the irreversible oxidation product of α-tocopherol, is only present in traces in animal tissues (see Diplock *et al.*[10]).



(IV)

Many workers, searching for evidence of a reversible oxidation-reduction reaction of α-tocopherol in tissues, have examined this quinone for activity of vitamin E and reported it to be inactive[14]. However, there seems superficially to be no obvious reason why it should not be as easily degradable to tocopheronolactone as α-tocopherol itself, and if this is so it also should be effective in increasing ubiquinone-levels. Accordingly, we prepared a specimen of α-tocopherylquinone and purified it until it was rigorously freed from any traces of reducing material and was chromatographically homogeneous. When it was given orally to vitamin E-deficient rats (10 mgm. to each animal), it increased ubiquinone-levels markedly, in the same way as tocopherol. Moreover, analysis of the tissues showed conclusively that no conversion to tocopherol had occurred, nor could the presence of tocopherylquinone itself be detected.

It seemed therefore that the reason for the lack of vitamin E activity of α-tocopherylquinone might reside in the inability of the animal to store or transport it. In order to study this possibility, the quinone was examined in a rat gestation-resorption assay test in the following manner. Virgin female vitamin E-deficient rats (4–5 months old) were mated and given 5 mgm. of the quinone (dissolved in propylene glycol/10 per cent ethanol) intraperitoneally and 5 mgm. of the quinone orally (in 'Tween 80' emulsion) every day between the 7th and 13th days of pregnancy. This dosage was completely effective in preventing fœtal resorption, proving that tocopherylquinone has vitamin E activity if given in adequate amounts to rats during gestation. We have recently become aware of the demonstration by Mackenzie and Mackenzie[15], using virtually identical methods, of the vitamin E activity of tocopherylhydroquinone, which these workers predicted by a process of reasoning quite different from ours. Their belief, however, that there is an essential difference between the quinone and the hydroquinone would now appear to be invalid: any quantitative discrepancies between the activity of quinone and hydroquinone can probably be explained by differences in the absorption and transport of the two substances. As a matter of history, the discovery of vitamin E activity for the quinone confirms the prognostication of Smith, Renfrow and Opie[16] made in 1942, when they found high biological activity for α-tocopheramine (which gives the quinone on oxidation). We have tried, so far without success, to demonstrate comparable activity for either tocopheronolactone or chromanol (III) (given intraperitoneally at 4 and 3 mgm./day respectively from the 7th to the 13th day of pregnancy) in the rat gestation-resorption test. In view of the solubility characteristics of the former and the rate at which it seems to be excreted, maintenance of adequate levels throughout the gestation period might be expected to be difficult and such levels may not have been attained with the small quantities of the lactone at present available to us.

Vitamin E and Lipid Peroxidation

It is now possible to discuss, in somewhat better perspective, the important question of the relation between the total biological function of vitamin E and its role as a lipid antioxidant. It has been the view of many workers that in fact the two functions are identical, but we believe that this view can no longer be accepted. We have shown previously[10,17] that the effect of tocopherol and selenium on ubiquinone is probably independent of any antioxidant role that vitamin E might have, and this is now further supported by the finding that tocopheronolactone is likely to be the active vitamin E metabolite controlling ubiquinone-levels. There is, of course, much nutritional and physiological evidence that undoubtedly suggests that α-tocopherol does play an important part in fat metabolism, protecting oxidizable lipids from destruction and perhaps preventing the accumulation of potentially toxic compounds in tissues. It seems reasonable to accept that α-tocopherol functions as a conventional lipid antioxidant, for at least some of its physiological effects can be duplicated by non-physiological antioxidants. However, in recent years, partly because of the many and persistent failures to demonstrate a more specific role for α-tocopherol in animals, it has proved tempting to explain the total role of vitamin E in terms of its antioxidant properties and to suggest that all the nutritional requirements for vitamin E can be satisfied by a physiological lipid antioxidant.

It is this hypothesis that we now wish to examine in some detail. Much of the evidence on which it is based stems from the demonstration that respiring mitochondrial preparations[18,19] and whole homogenates[20] exhibit a phenomenon usually referred to as 'lipid peroxidation' and that this can be inhibited by the *in vitro* addition of α-tocopherol, antioxidants, or certain metallic ions such as those of cobalt and manganese. Dietary supplementation with tocopherol has been shown, in a few instances, to reduce tissue peroxidation; and certain characteristic symptoms of vitamin E deficiency, such as rat erythrocyte hæmolysis[21] and impairment of ascorbic acid synthesis in rat liver[22] are always accompanied by an increase in peroxidation, and both are reversed *in vitro* by α-tocopherol. Lipid peroxidation itself appears to be poorly understood and is obviously a simple term for a complex process. *In vivo* peroxides and *in vitro* peroxidation (the latter after incubation of tissue preparations at 37° for periods varying between 15 min. and 1 hr.) are usually determined by adding thiobarbituric acid (TBA) and measuring the red colour produced. It is usually considered that the TBA-reacting substance is malonaldehyde[23]. The *in vitro* peroxidation is considered to be a 'development' of a process that has already produced changes in the tissues, and it is known to be greatly enhanced by the presence of ascorbic acid, which catalyses many peroxidations. Kitabchi *et al.*[22] have shown that peroxidation in tissues is mainly microsomal in origin, the malonaldehyde being produced by a reaction between a microsomal lipid and a metal ion or an intermediate formed from gulonolactone or ascorbic acid. They suggest that peroxidation is closely related to the impairment of ascorbic acid synthesis that occurs in vitamin E deficiency.

We have already discussed certain aspects of the antioxidant theory[5] and have shown that study of the tocopherol concentrations in different tissues leads to the conclusion that there is no real relationship between these concentrations and the extent of lipid peroxidation. For example, the rat adrenal contains several times as much tocopherol as any other tissue in the body and yet peroxidizes very easily[24]. Moreover, in most tissues of the rabbit[19] and also in the rat[24], there are no significant differences between the *in vivo* peroxides of vitamin E-deficient and adequately fed animals. It has been suggested[19] that the TBA reactants found in the tissues of adequate animals do not represent lipid peroxidation products; but this appears to involve a circuitous argument, and, as we show below, they are in fact indistinguishable from the 'peroxides' of deficient animals. It is agreed by all workers who have investigated the phenomenon that whereas *in vitro* lipid peroxidation can easily be prevented in liver and perhaps muscle by the addition of tocopherol to deficient diets, such an effect cannot be obtained in other tissues. For example, Carpenter *et al.*[20] found that rat testis, a tissue particularly susceptible to the effects of vitamin E deficiency, synthesized peroxides *in vitro*, even when taken from animals given sufficient tocopherol to prevent deficiency. Bieri and Anderson[25] had to feed relatively huge amounts of tocopherol for long periods to prevent lipid peroxidation in rat testis and even then they were unable to effect any appreciable reduction in brain and kidney.

Table 6 summarizes the results of an experiment in which we have studied lipid peroxidation in pregnant female rats from the stock breeding colony and similar rats from the vitamin E-deficient colony. Both groups were mated and pregnancies allowed to continue to the 18th day: this is the time at which rats are normally examined in the standard rat gestation-resorption assay for vitamin E and resorbed

Table 6. LIPID PEROXIDATION IN STOCK COLONY AND VITAMIN E DEFICIENT PREGNANT RATS

Group	Test	Liver	Uterus*	Fœtus	Placenta
Stock colony	*In vivo* peroxides	6 (2)	3 (5)	4 (5)	4 (2)
	In vitro peroxidation†	12 (5)	5 (5)	10 (3)	5 (2)
	In vitro + ascorbate‡	12 (5)	5 (7)	19 (4)§	5 (2)
				(Total uterine contents)	
E-deficient	*In vivo* peroxides	10 (13)	4 (4)	5 (4)	
	In vitro peroxidation†	22 (5)	9 (3)	7 (1)	
	In vitro + ascorbate‡	34 (12)	17 (6)	22 (4)	

Results are given as direct readings of the optical density at 520 mμ, after reaction of 4 ml. of a 2 per cent homogenate with TBA. Each result is a mean followed by number of rats separately tested.

* This tissue could not be homogenized and was used as a fine suspended mince.

† Incubation time of 15 min. for liver, 60 min. for other tissues.

‡ 3×10^{-6} mole of ascorbic acid added before incubation.

§ One discordant result was found in another rat in this group.

fœtuses counted. The rats were killed and liver, uterus, placenta and live fœtuses taken from the stock animals, and liver, uterus and total uterine contents (combined resorbing fœtuses and placentæ) from the deficient group. Individual tissues from each animal were examined for *in vivo* peroxides and *in vitro* lipid peroxidation by methods described in detail elsewhere[21,26]. In all the tissues of the deficient animals, peroxidation increased after *in vitro* incubation, particularly in the presence of ascorbate. In the adequate animals, however, although peroxidation was low in liver, uterus and placenta, the viable fœtuses peroxidized almost as much as the total resorbed uterine contents of the vitamin E-deficient group. It is especially significant that this fœtal peroxidation in the adequate tissues increased in the presence of ascorbic acid (compare liver and uterus, where it did not), suggesting quite strongly that the phenomenon is identical with the 'lipid peroxidation' of deficient tissues. The significance of this experiment is that the viable 18th-day rat fœtus, *by classical definition,* contains sufficient vitamin E for all its needs and the conclusion must be that, at least in this instance, the TBA reaction cannot bear any relation to vitamin E function.

It would in fact appear from the series of experiments now to be described that even the 'inhibition' of lipid peroxidation may not prove to be explicable solely in terms of the reducing or antioxidant properties of α-tocopherol itself. In these experiments, the results of which are given in Table 7, a number of substances were examined for their activity in preventing the *in vitro* peroxidation of vitamin E-deficient rat liver homogenates. The substances tested clearly fall into two groups: (1) those as active as α-tocopherol, which include only thyroxine and, most remarkably, the non-reducing substance, tocopheronolactone, and (2) those with only about one-tenth of the activity of tocopherol, which comprise the ubiquinones, ubichromenol, α-tocopherylquinone, the quinone reduction products (quinols), vitamin A, and menadione. The quinols were obtained from the corresponding quinones by reduction in ethanol with aqueous potassium borohydride and maintained in the reduced state with an excess of reagent (pilot tests showed that borohydride had no significant effect in preventing peroxidation).

The results show that conversion of the quinones to quinols only enhances the activity very little. This may be because the quinones are, in any event, mainly reduced to quinols under the conditions of test: ubiquinone can be reduced by many substrates[27], and both menadione[28] and tocopheronolactone[29] can be enzymatically reduced by diphosphopyridine nucleotide. The evidence, however, is not incompatible with the assumption that the non-reducing quinones themselves may participate in the inhibition of 'lipid peroxidation'. For example, it has not so far proved possible to demonstrate that tocopherylquinone can be reduced either *in vivo* or by *in vitro* biochemical systems[30,31]. It was considered as a possibility that the activity of tocopherylquinone could be accounted for by an enzymatic cleavage to tocopheronolactone under the conditions of incubation: however, when tocopherylquinone was pre-incubated for 60 min. with a liver homogenate and then re-tested for its effect on peroxidation in a fresh homogenate, only a small enhancement of activity could be demonstrated.

Another interesting observation from Table 6 is that vitamin A has 'antioxidant' activity, as measured by the 'lipid peroxidation' test, although it is a substance that can scarcely be considered as a conventional antioxidant: it is difficult to see why the addition of an unsaturated lipid like vitamin A should protect against peroxidation (although we have observed similar effects at a higher concentration with substances such as nerolidol, farnesol and geranyllinalool).

Since vitamin A is an important constituent of liver, which has not only been extensively used for studies of peroxidation but also provides a good deal of the evidence for the effect of vitamin E, it seemed important to examine its influence on 'lipid peroxidation' in this tissue. Three groups of male rats were placed, at the age of 21 days, on a diet deficient in both vitamin E and vitamin A. After a month, one group was transferred to the same diet supplemented with 10 I.U. of vitamin A/gm., the second group to the same diet supplemented with 40 I.U. of vitamin A/gm., and the third group remained as vitamins A- and E-deficient controls. After a month on these diets, the rats were killed and livers and brains pooled for studies of their 'lipid peroxidation'. As Table 8 shows, there was indeed a marked 'antioxidant' effect in both tissues containing vitamin A: this is doubly remarkable since, as we show elsewhere[26], the *vitamin E* concentration in liver deficient in vitamins A and E may be several times higher than in control livers deficient only in vitamin E (because of the well-established antagonistic effect of vitamin A on tocopherol). The same is true of brain; and, in fact, in this tissue the 'antioxidant' effect of dietary vitamin A is at least as great as we have ever obtained with dietary vitamin E (see also Bieri and Anderson[25]). It can be concluded, therefore, that vitamin A must also be considered as a factor in reducing 'lipid peroxidation' as measured by the TBA test, particularly since the addition of tocopherol to homogenates protects vitamin A from destruction.

Table 7. EFFECT OF α-TOCOPHEROL, TOCOPHERONOLACTONE AND SOME QUINONES ON INHIBITION OF *in vitro* LIPID PEROXIDATION IN LIVER HOMOGENATES

	Per cent reduction in peroxidation (TBA test)	Amount of active substance used (moles)
α-Tocopherol	94	5×10^{-7}
	c. 50	$2\text{–}4 \times 10^{-8}$
Substances as active as α-tocopherol		
L-Thyroxine sodium salt	93	5×10^{-7}
	c. 50	2×10^{-8}
Tocopheronolactone	79	1×10^{-6}
	c. 50	2×10^{-8}
	36	1×10^{-8}
Reduced tocopheronolactone (quinol)	25	1×10^{-6}
Substances with about one-tenth or less of the molar activity of α-tocopherol		
α-Tocopherylquinone	40	2×10^{-7}
	9	2×10^{-8}
α-Tocopherylhydroquinone	25	2×10^{-8}
Ubichromenol 50	32	2×10^{-7}
Ubiquinone 30	20	4×10^{-7}
Ubiquinone 35	31	4×10^{-7}
Ubiquinone 40	23	4×10^{-7}
Ubiquinone 45	13	4×10^{-7}
Ubiquinone 50	19	4×10^{-7}
Ubiquinol 45	0	4×10^{-7}
Ubiquinol 50	8	4×10^{-7}
Menadione	76	5×10^{-7}
Vitamin A alcohol	44	2×10^{-7}
Vitamin A palmitate	81	1×10^{-6}
Vitamin K_1	56	1×10^{-7}

Table 8. EFFECT OF DIETARY VITAMIN A ON 'LIPID PEROXIDATION' OF RAT LIVER AND BRAIN

	Peroxides† (E at 520 mμ)					
	Liver‡			Brain‡		
Level of dietary A, I.U./gm.	0	10	40	0	10	40
In vivo test	4	2	2	2	1	1
Incubated at 37°	17	21	13	42	37	28
Incubated with ascorbate*	51	38	27	118	120	91

* 3×10^{-6} mole of ascorbic acid in 4 ml. of homogenate.
† Each result is a mean of two determinations.
‡ Liver incubated for 15 min., brain for 60 min.
For details of diets, see text. Results are given as direct readings at 520 mμ of the TBA reaction.

The picture of 'lipid peroxidation' is still further complicated by considerations of another series of experiments (summarized in Table 9), in which tocopheronolactone and tocopherylquinone were examined for their activity in preventing erythrocyte hæmolysis in rats. This hæmolysis, which is produced by incubation with dialuric acid, is an early and characteristic symptom of vitamin E deficiency in the rat[32] and can be completely reversed if the cells are pre-incubated *in vitro* with α-tocopherol or if the animal is given vitamin E orally some time before the blood is taken. Many other substances, some of them non-reducing, can also inhibit hæmolysis[33] and this inhibition is always accompanied by a decrease in the lipid peroxidation (thiobarbituric acid reaction) of the erythrocytes[21]. As Table 9 shows, tocopheronolactone and tocopherylquinone were both negligibly active when given orally ; but the latter substance, in strong contrast to the former, was found to be quite active *in vitro* both in inhibiting hæmolysis and in reducing peroxidation. Now, lipid solubility *per se* is not a factor that determines the *in vitro* activity of substances in the hæmolysis test : we have shown[33], for example, that ubiquinone 50 is inactive, whereas thyroxine affords complete protection[21]. It is, moreover, unlikely (judging from the results in Table 7) that tocopherylquinone is more easily reduced to a quinol on the surface of the erythrocyte than tocopheronolactone would be. While these results are not easy to interpret, they provide still further evidence that the relation between the effect of antioxidants and 'lipid peroxidation' on one hand and between 'lipid peroxidation' and the thiobarbituric acid reaction on the other needs to be reconsidered.

Table 9. EFFECT OF TOCOPHERONOLACTONE AND α-TOCOPHERYLQUINONE ON RAT ERYTHROCYTE HÆMOLYSIS, *in vivo* AND *in vitro*

Substance	*In vivo* potency (D-α-tocopheryl acetate = 100)	*In vitro* potency (DL-α-tocopherol = 100)	Protection, *in vitro* against peroxidation
Tocopheronolactone	< 10 (if any)	< 1 (if any)	Nil
Tocopherylquinone	< 3 (if any)	*c.* 10	complete
Tocopherylhydroquinone	< 3 (if any)	—	—

Possible Functions of Vitamin E

Although it is still difficult to present a unified concept that will explain satisfactorily the role of vitamin E in animals, several developments in the past two or three years signify a new approach to the problem that will certainly prove to be most productive. In our opinion, the present position may be summarized as follows: Vitamin E must have at least two functions, which at present have to be considered independently, but which may prove to be closely related. One is concerned with the metabolism of unsaturated lipids, in which role its antioxidant properties probably play a part : however, the connexions between this function and the phenomenon that occurs in tissues and is termed 'lipid peroxidation' seems to us, for many reasons, still to be obscure and may yet prove to be an example of a biochemical truism. It is perhaps not altogether surprising that this should be so. It is only necessary to examine the findings by Carpenter *et al.*[20] and Kitabchi *et al.*[22] on the relation between tocopherol and ascorbic acid synthesis to appreciate the subtleties that might be involved in the TBA reaction. Thus, tocopherol increases the synthesis of ascorbic acid, which itself catalyses fatty-acid peroxidation and inhibits its own synthesis[22] : tocopherol inhibits malonaldehyde production, but ascorbic acid increases it markedly[22] : and, contrarily, ascorbic acid enters into a potent synergistic relationship with tocopherol in preventing the hæmatin-catalysed peroxidation of unsaturated fatty acids[34] : the possibilities of feedback mechanisms are obviously many and intricate.

The second function of vitamin E, in which the active substance is almost certainly a metabolite of α-tocopherol, possibly tocopheronolactone, results in the biogenesis of ubiquinone. Two key questions immediately present themselves : How far is it possible to understand the physiological and histopathological symptoms of vitamin E deficiency (with the exception of those relating in the narrow sense to lipid antioxidant effects) in terms of ubiquinone deficiency ? Is the effect of tocopherol on ubiquinone a unique effect on its synthesis or only a secondary phenomenon resulting from a more fundamental process elsewhere ? Although answers to these questions must await further work, it is reasonable even now to suggest that at least some of the disturbances in respiration, oxidation, and tissue (particularly embryonic) differentiation in vitamin E deficiency states may be explicable in terms of the effect on ubiquinone-levels. In the rat, and probably in other species, there is an alternate mechanism, involving selenium, which also influences biosynthesis of ubiquinone. The two mechanisms appear to be parallel, since in most tissues of the adult rat, as shown elsewhere[26], tocopherol does not increase ubiquinone-levels if sufficient selenium is present and *vice versa*. In two organs, however, the two mechanisms are plainly of unequal importance. In uterus, the selenium-dependent process does not appear to be present at all, whereas in liver, where selenium exerts a remarkable influence on ubiquinone compared to that of tocopherol[8,10,26], the selenium-dependent mechanism is apparently preponderant. Such a difference between the effects of selenium and tocopherol is also found in the livers of avian species (to be discussed in a separate communication).

The existence of such alternate biochemical systems and the possibility that they may be of unequal significance in different tissues might account for the observed differences between the physiological effects of selenium and tocopherol in animals. It is at this stage not possible to say whether all animals require a supply of both tocopherol and selenium. The answer to this question may not only vary from species to species but also may differ at different periods during the life-cycle. Thus the rat needs tocopherol specifically for reproduction (and perhaps during very early life), but during adult life its needs could conceivably be met by selenium. According to Nesheim and Scott[35] the chick has an absolute requirement for selenium even if tocopherol is supplied, and a similar position may exist in the lamb. Both Draper *et al.*[36] and, more recently, Crider *et al.*[37] have concluded that the rat does not need tocopherol if certain antioxidants are provided in the diet and that substances such as DPPD (N,N′-diphenyl-*p*-phenylene diamine) and ethoxyquin (1,2-dihydro-6-ethoxy-2,2,4-trimethylquinoline) can prevent reproduction failure in the rat.

We have analysed lard-casein diets identical in composition with those used by these workers, however, and have found them to contain enough tocopherol to supply about 40–70 μgm. per week to each rat. These amounts cannot be considered insignificant. Furthermore, as we have demonstrated elsewhere[26], ethoxyquin added to these so-called 'vitamin E-free' diets (especially those containing considerable amounts of vitamin A[36,37]) effectively spares tocopherol in rat uterus and in fact raises it to levels not incommensurate with it having some biological activity. Bieri *et al.*[38] have likewise suggested that the chick does not need tocopherol; but we have found that the diets used by these workers also contain appreciable amounts of tocopherol and that animals fed on them show significant tissue concentrations (to be published). There is no doubt that many of the discrepancies in these investigations—as well as the continued use of diets incorrectly believed to be free of vitamin E—stem largely from the use of inadequate analytical methods: only the more recently developed chromatographic procedures can deal satisfactorily with the small quantities of tocopherol relevant to investigations of vitamin E-deficient animals. It would seem that, if the absolute requirement of both the rat and the chick for α-tocopherol is to be determined, there is no alternative to the use of wholly synthetic diets. (In this connexion, even the methyl linoleate urea complex (Hormel Foundation), used by Crider *et al.*, has been found to contain about 3 μgm./gm. of α-tocopherol (and, in addition about 5 μgm./gm. of ubiquinone) which amounts are consistent with its method of preparation. The concentrate used by Draper *et al.* may have contained similar quantities. These figures illustrate some of the difficulties in work on vitamin E.)

Returning once more to the biochemical function of tocopherol, two points of interest need to be mentioned. First, is there any connexion between tocopherol and cholesterol synthesis? This much-neglected topic presents itself afresh in view of the contrasting effects of fasting on ubiquinone-levels and cholesterol synthesis, already referred to. There is already an area of confusion here: many workers[39,40] have shown that tocopherol has a marked hypocholesteræmic effect in the rabbit, but other workers[41] could not demonstrate this in the rat, whereas the results of Gray *et al.*[42] suggest that tocopherol might increase cholesterol synthesis in the rat. Secondly, is it possible to correlate the effect of vitamin E on ubiquinone with the demonstration by Corwin and Schwarz[9] that the decline in the oxidation of α-ketoglutarate by vitamin E-deficient liver homogenates can be prevented by *in vitro* addition of α-tocopherol, tocopheronolactone or menadione? Neither vitamin K deficiency nor menadione supplementation affects ubiquinone-levels in the rat (unpublished observations; see also Morton and Phillips[43]) and, furthermore, Corwin and Schwarz found dietary selenium to be inactive in restoring oxidation. It is possible, therefore, that although the effect of dietary selenium and tocopherol on hepatic necrosis may be related to their common role in ubiquinone biogenesis or processes leading to it, the effect of tocopherol in restoring respiratory decline in slices and of the ketoglutarate system may be due to yet another function of tocopheronolactone.

PHOTOCHEMICAL SYNTHESIS OF AMINO-ACIDS AND A NEW TRANSAMINATION PROCESS BY TRANSFER OF FREE AMINO-RADICALS

By GIOVANNI FERRARI and PROF. ROLANDO CULTRERA
Institute of Agricultural Chemistry, University of Padua

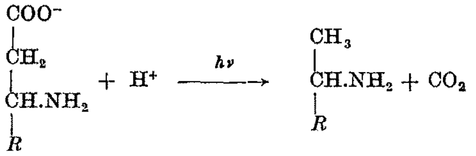
RECENT investigations conducted in our Institute[1-3] have shown that it is possible to synthesize amino-acids by ultra-violet irradiation of solutions containing a ternary organic compound together with a nitrogen compound, such as potassium nitrate, sodium nitrite, hydroxylamine and ammonium hydroxide. All the various steps of the photochemical process have been elucidated; the action mechanism of each of them has been established exactly, and a rational, co-ordinated interpretation has been deduced.

For reasons of brevity we report in Table 1 only a few examples of the syntheses accomplished by us.

Further investigations, which will be published in full in *Gazzetta Chimica Italiana*, have given results which we regard as interesting.

Amino-acids in acidified aqueous solution, when exposed to ultra-violet rays, undergo various changes, above all (scheme 1):

(1) Decarboxylation:

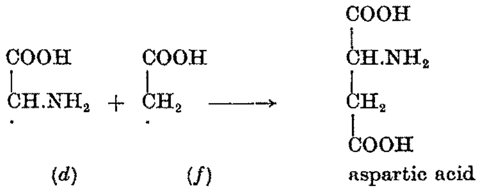


$$\begin{array}{l}COO^-\\ |\\ CH_2\\ |\\ CH.NH_2\\ |\\ R\end{array} + H^+ \xrightarrow{h\nu} \begin{array}{l}CH_3\\ |\\ CH.NH_2\\ |\\ R\end{array} + CO_2$$

Scheme 1

(2) Radical decomposition by homolytic degradation, for example, scheme 2:

(3) Recombination of radicals, with formation of new amino-acids: the free radicals may recombine in the most varied ways, for example, scheme 3:



$$\underset{(d)}{\begin{array}{l}COOH\\ |\\ CH.NH_2\\ \cdot\end{array}} + \underset{(f)}{\begin{array}{l}COOH\\ |\\ CH_2\\ \cdot\end{array}} \longrightarrow \underset{\text{aspartic acid}}{\begin{array}{l}COOH\\ |\\ CH.NH_2\\ |\\ CH_2\\ |\\ COOH\end{array}}$$

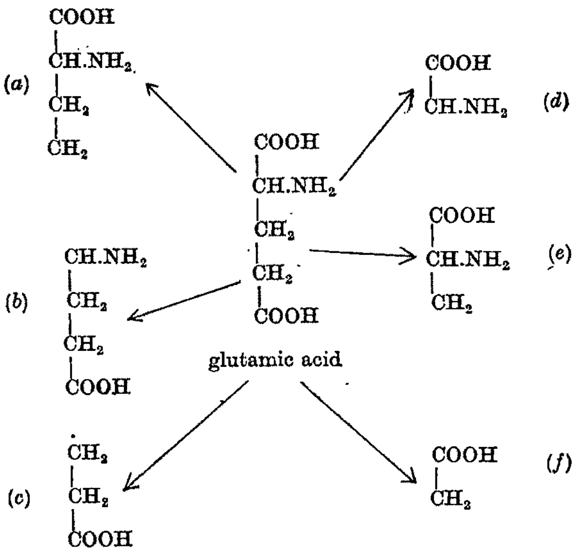
Scheme 3

Thus the radicals containing the amino-group may become 'transamination agents', in that they can determine the transfer of properties of the amino-group from one amino-acid to another of different molecular structure.

If the solution containing the amino-acid is irradiated in the presence of a properly chosen organic compound, capable, in its turn, of yielding free radicals, it is possible to direct the transamination process toward the formation of determinate synthesis products.

Table 1

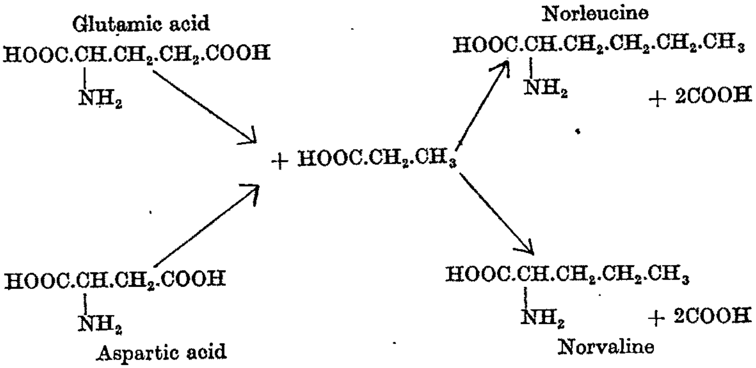
Organic substance irradiated with ultra-violet rays	Nitrogen compound present in the solution	Amino-acids obtained
Glutaric acid	KNO$_3$, KNO$_2$, NH$_2$OH	Glutamic acid, glycine, β-alanine, γ-aminobutyric acid, aspartic acid
Citric acid	KNO$_3$, KNO$_2$, NH$_2$OH	Glycine, β-alanine, serine, aspartic acid, γ-aminobutyric acid
Glucose	KNO$_3$, KNO$_2$, NH$_2$OH	Serine, glycine, aspartic acid



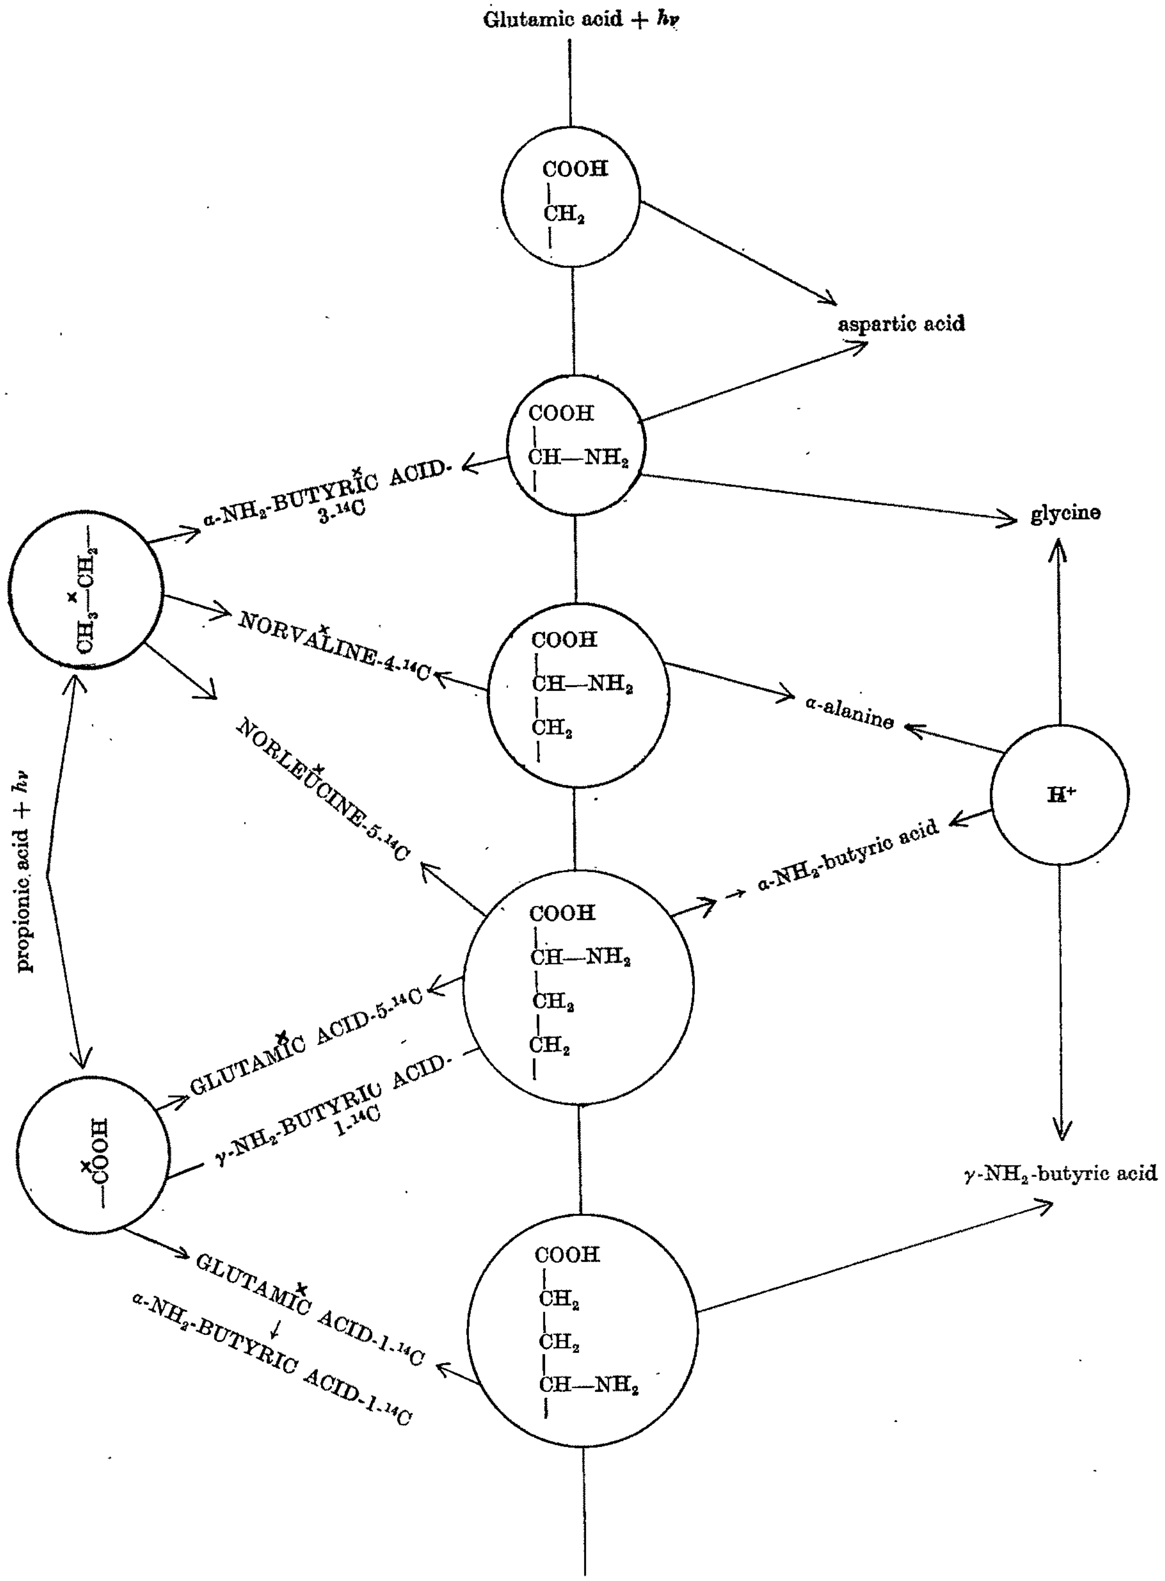
Scheme 2

For example, we have synthesized norleucine by irradiating glutamic acid in the presence of propionic acid, and have synthesized norvaline by irradiating aspartic acid in the presence of propionic acid

The scheme of the reactions involved is shown in scheme 4:



Scheme 4



Scheme 5

Capital letters, radioactive compounds; small letters, non-radioactive compounds. +, radioactivity from propionic acid-1-^{14}C; ×, radioactivity from propionic acid-2-^{14}C.

(As has been experimentally established, the two —COOH radicals form oxalic acid.)

In order to demonstrate the mechanism of the process described we have employed both the chromatographic detection of the synthesized compounds and the isotopic tracer method. For the latter purpose we have used two types of propionic acid labelled with carbon-14 in positions 1 and 2, respectively ($CH_3.CH_2.\mathit{C}OOH$ and $CH_3.\mathit{C}H_2.COOH$).

In all cases we have obtained a variety of amino-acids; but the examination of the autoradiographs obtained from the chromatograms has shown that the major part of the radioactivity is concentrated in the norvaline coming from aspartic acid and propionic acid-2-^{14}C, while the norvaline coming from propionic acid-1-^{14}C is completely inactive. Similar results have been obtained with the norleucine coming from glutamic acid + propionic acid. We have therefore succeeded in demonstrating the effect we sought.

We report the recombination scheme for the radicals obtained by exposing to ultra-violet rays the solution of glutamic acid + propionic acid-1-^{14}C and -2-^{14}C (Scheme 5). In the scheme the radicals are indicated, for simplicity, with an interrupted valence bond, whether they are actual free radicals formed by homolytic decomposition or ionic-type radicals due to heterolytic decomposition.

The new transamination process appears to be much more efficient than the conventional one, on account of the variety of amino compounds to which it can give rise.

As an example we may compare the possibilities of the system glutamic acid + oxalacetic acid within the framework of conventional transamination with those of the analogous system glutamic acid + succinic acid within the framework of radical transamination. In the former case only aspartic acid can be obtained, whereas in the latter case nine amino-acids can be formed, namely, aspartic acid, α-aminopimelic acid, γ-aminopimelic acid, α-aminoadipic acid, γ-aminoadipic acid, α-alanine, glycine, α-aminobutyric acid and γ-aminobutyric acid.

MEASUREMENT OF FUNGICIDAL EFFECTS IN FIELD TRIALS

By R. W. RAYNER

Commonwealth Mycological Institute, Kew, Surrey

DURING field trials on the control of coffee rust (*Hemileia vastatrix* B. et Br.) at the Coffee Research Station, Ruiru, Kenya, special methods were devised to obtain maximum sensitivity by minimizing the effects of localized, natural variability in rust, attack intensity. These methods are of general application, and may be adapted for use with other diseases. The very considerable local variation of rust attack found is, perhaps, remarkable if, as has been generally supposed, spore dispersal is predominantly by wind. However, recent research[1-3] has shown that most air-borne spores probably do not travel far and has indicated rain-splash as important for spore dissemination.

The degree of rust infection is best expressed as the number of spore-producing, individual, infection loci per unit of leaf area and is approximately equal to the number of lesions per leaf if the proportion of overlapping mycelia is low. The relationship to the percentage of infected leaves, which is easier to determine, was examined.

A representative sample of 100 leaves was taken from five trees in each plot of a six treatment, four times replicated randomized block, spraying experiment showing considerable differences in the level of rust attack, and was recorded for the numbers of leaves having respectively one, two, three, etc., rust lesions per leaf. The lesions were generally fairly small and scattered so that undetected overlapping was negligible. The cumulative frequency distribution curves for the percentage of the total number of leaves in each category of rust lesion number per leaf were plotted on a probit scale for each plot (Fig. 1). For a low percentage of leaves infected, a straight line indicating a truncated normal distribution is approximated. As the percentage increases so the truncation is less and the degree of curvature is more pronounced, indicating increasing divergence from normality due to the greater development of the upper 'tails' of the distributions. The relation between the percentage of rusted leaves and the number of lesions per 100 leaves is thus exponential (Fig. 2) instead of sigmoid, as it would have been had the distributions remained normal. Similar results from a locality in a climatically different area showed the same relationship. Thus one measurement may be regarded as a transform of the other.

The percentage of rusted leaves may in fact be a better measure of the effect of rust attack on the tree, as evidence has been obtained of a direct relation to foliage density. Thus, in one trial, the relation between the percentage of rusted leaves in May and the number of mature leaves per mature branch (that is, one on which leaf shedding had commenced) gave a regression coefficient of $-0{\cdot}98^{**}$, that is, for each leaf rusted in May, there was nearly one less present in September. Further, in other investigations, not however concerned with rust, strong correlations between foliage density and crop yield have been found.

In order to obtain a representative sample of leaves, account must be taken of the different leaf densities in different parts of the tree. In the above investigation, a method devised for investigation of fungicide cover, etc., was used. The total number of primary branches (that is, those originating on the trunk) per tree was counted. Every second, third, etc., primary was sampled, the interval increasing with the total number present. From the trunk, a path was traced out along one side of each primary sampled, up one side of any laterial branch or lateral on this and back down the other side to its base and finally back down the opposite side of the primary, so that the whole branch system was systematically traversed. Along this path, every 10th, 20th, etc.,

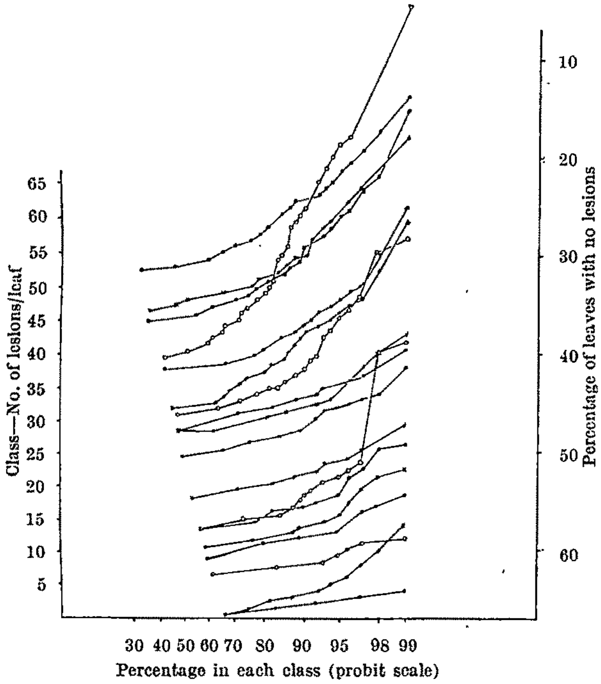

Fig. 1. Probit cumulative frequency distribution curves for eighteen plots of coffee trees, showing the percentage of the total number of leaves examined which occurred in each 'number of lesions per leaf' class. Each curve is displaced upwards to an amount proportional to the percentage of leaves with no lesions, so as to exhibit the change in form of the curve with this latter factor

leaf passed was removed according to the size of the tree, to obtain a sample of 20–30 leaves. This was reduced to 20 by discarding at random.

For field trials a similar, but less laborious, systematic sampling system was used. Five trees in each plot were roughly divided by eye into five radial sectors and five horizontal zones. On the first tree, the lowest primary in the lowest zone was traversed as before, on the second tree the middle primary in the next sector and next zone and so on. Each mature leaf traversed was examined and recorded if attacked by rust. One hundred leaves were inspected on each primary (the adjacent primary being included if necessary), a total of five hundred leaves in each plot. The resulting percentage infection was somewhat biased by over-representation of the lower regions of the tree since these have fewer leaves. Hence some over-estimation of rust attack probably resulted since more rust occurs in this region. As the trials were concerned with comparisons of treatments, this was of little importance, and it was possible for one man to record completely a large factorial trial of 42 plots and 920 trees in a few days.

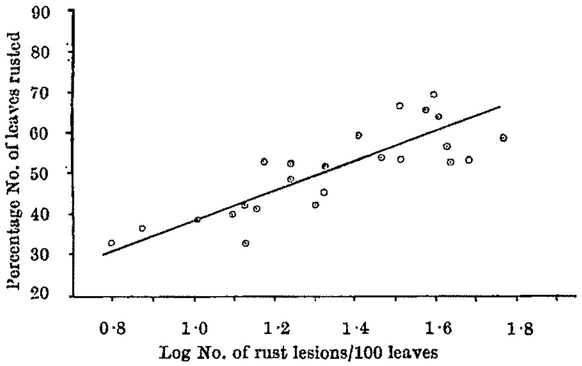

Fig. 2. The relation of the percentage of leaves with rust to the logarithm of the total number of rust leaves per hundred leaves

That incidence of rust in the field is strongly localized is clearly shown by observations made in three field trials. In these, the design could be treated as consisting of plots of two rows of ten trees each. Rust was sampled in each row on alternate, unsprayed trees, the other trees being sprayed. The standard error between the pairs of rows (sub-plots) was considerably less than between plots, being 63·8, 44·2 and 41·9 per cent lower in the three trials. The differences between the plots were, in accordance, very highly significantly greater than would have been expected from the differences between the sub-plots. Correlation between the sub-plots is thus present, the coefficients being 0·877***, 0·522** and 0·490*** respectively. These results suggest a distribution of rust attack by dispersal from centres of infection within the area rather than by mass infection arriving from outside. The correlation between sub-plots suggests that the measurement of rust intensity on a half of each treated plot in a field trial of the effects of fungicides could be used to correct that on the treated half for local variations using covariance, and hence increase the sensitivity of the trial. The effect was measured in the trials, omitting treated trees. The standard errors were reduced by 51·1, 15·1, and 11·9 per cent. The experimental area was divided into three blocks, and some reduction in standard error was obtained from this alone (14·1, 18·3 and 0·5 per cent), but in each case using covariance additional reduction (36·3, 5·7 and 11·8 per cent) resulted. Thus the relative usefulness of the two methods for the reduction of standard error varied from trial to trial, depending on the pattern of local variation in rust intensity.

Covariance analysis, although affording a useful approximation, is not strictly applicable when treatments are actually applied, since the greater the treatment effect the lower the rust intensity and the less the effect of the unsprayed level. The regression coefficient would be expected to range from 1 to 0, varying directly with the percentage of control. This was, in fact, found to be the case when data from one trial were examined critically. The correct adjustment is thus obtained if the rust-levels on the treated halves of the plots are expressed as a percentage of those on the untreated halves. A difficulty arises if the rust-level on individual unsprayed plots falls to a level very considerably lower than is general. Small differences between sprayed and unsprayed halves will then be disproportionately exaggerated and the apparent sensitivity of the trial will be unduly decreased. The use of an index of relative disease incidence, the ratio of the differences between sprayed and unsprayed halves to their sum, which amounts to a simple transform of the percentage, was found useful in such a case.

The degree of disease control exerted by a given treatment or treatment combination over the whole trial is more precisely estimated by summing the rust intensity on the respective sprayed halves of the plots and expressing this as a percentage of that on the unsprayed halves, rather than summing and averaging the percentage reduction of rust intensity on each individual plot, these latter data being reserved to estimate the significance of the differences. Some heterogeneity of variance was found and account was taken of this, sometimes by employing a transformation, but the effects were only slight.

The effectiveness of the methods used may be judged from the results of a factorial trial with three replications in which two fungicides at four concentrations equivalent to $\frac{1}{4}$, $\frac{1}{2}$, 1 and 2 per cent Burgundy mixture were contrasted for application to upper and lower leaf surfaces. Local variation in rust attack was considerable, the coefficient for the untreated plot halves being 56·5 per cent. The linear effect of concentration was very highly significant and differences between the effects of the fungicides estimated as equivalent to those produced by the difference between 1 and 1·3 per cent concentrations were detectable. In another trial with three replications of $\frac{1}{2}$, 1 and 2 per cent concentrations of three fungicides with upper and lower surface applications, differences equivalent to that between 1 and 2·6 per cent in one season and 1 and 2·1 per cent in a second season were detectable.

The observation discussed shows that intensity of rust attack may be estimated from the percentage of rusted leaves per bush, since there is evidence that this is mathematically related to the number of rust mycelia per leaf. It is probably directly related to effects on foliage density, which in turn is related to crop yield.

The sensitivity of field trials on the fungicidal control of rust disease may be considerably increased when local variation in intensity of attack is marked, by assessing this variation from estimates of rust intensity on alternate, unsprayed trees in each plot. The procedure increases the accuracy of the estimates of degree of control. Further, it should reduce the effects of any reduction in inoculum production resulting from a spray treatment on one plot on the inoculum-level in neighbouring plots.

The design was very satisfactory for differentiating between treatments where the aim was to assess the amount of protection against infection afforded by each. If, however, it is required to estimate the effects, especially as regards timing, on the rate of build-up of infection and this is influenced to any considerable extent by the amount of inoculum movement from tree to tree, the method may be unsatisfactory except for estimating 'within tree' effects and the amount of the inoculum movement. A method of dealing with this difficulty might be to use square plots in which the effect of varying the number of trees in a central sprayed group surrounded by unsprayed trees would be determined, and allowance made for the estimated effects of area sprayed on rate of build-up of attack by the disease.

PREDICTION OF THE EFFECT OF LIGHT-TIME FRACTION ON THE CRITICAL FLICKER FREQUENCY; AN INSIGHT FROM FOURIER ANALYSIS

By K. GIBBINS and Dr. C. I. HOWARTH
Department of Psychology, University of Hull

THE study of the response of the human eye to flickering light has notoriously produced a number of extremely complex and confusing results. This article shows how at least part of the confusion can be resolved by the application of simple physical principles to the problem. At least two workers[1-3] have commented recently on the particularly chaotic results found in investigations of the relationship between the light-time-fraction (L.T.F., sometimes misleadingly called light-dark-ratio) and the critical flicker frequency (C.F.F., that is, the fastest frequency at which flicker is just perceptible). A sample of these results as summarized by Landis[3] is shown in Fig. 1. We suggest that the confusion can be understood and ordered by considering the Fourier analysis of the stimuli with different L.T.F.'s. In the present case, all we wish to do is to point out that a train of stimuli near fusion (the C.F.F. condition) can be considered to contain two different components: (*a*) a steady component (the first Fourier component) which is the mean intensity of the light and which we shall call I_M; (*b*) a fluctuating component (consisting of the second and higher Fourier components). This we shall call I_F.

The steady term I_M can be considered as a background illumination (or adaptation-level) and must have the effect of masking the fluctuating part, I_F, and thus of reducing the C.F.F. if I_F is held constant. I_F, on the other hand, is the effective stimulus and for a constant I_M, increasing I_F must increase the C.F.F. The crux of our argument is that complementary L.T.F.'s (for example, 0·1 and 0·9, or 0·3 and 0·7) are identical in the amplitude of their flickering components but differ in the amplitude of the steady components; 0·9 L.T.F. is much brighter than 0·1 L.T.F. since its I_M is nine times greater. Two things follow from this. First, we would predict that if the reduction in I_M for short L.T.F.'s is compensated by the addition of a steady light to the flickering light, the C.F.F. for complementary L.T.F.'s should be equal. Secondly, if we knew the effect of changing I_M, while holding I_F constant, we should be able to predict the shape of the curve of L.T.F. against C.F.F. for the uncompensated condition.

Other workers[4-6] have attempted to compensate for the obvious difference in brightness by varying the intensity of the flickering light. In our terms this is an illogical procedure, since, although I_M is now held constant, I_F varies inversely with the L.T.F. It is therefore not surprising that all these workers found C.F.F. higher for 0·1 L.T.F. than for 0·9. If no compensation of any kind is attempted, 0·1 still usually has a higher C.F.F. than 0·9. In this case it is because I_M varies with L.T.F. and the higher I_M masks the constant I_F and hence reduces the C.F.F.

To test our hypothesis we have repeated the experiments reported by previous workers and have managed to obtain most of the forms of relationship reported previously. Then we compensated by adding

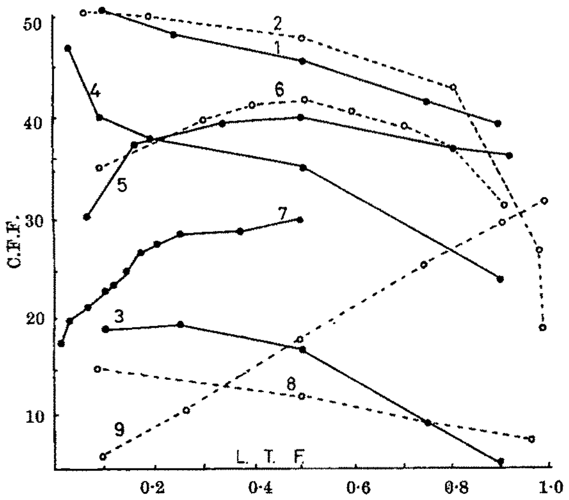

Fig. 1. Landis's (1954) summary of previous data. Effect of L.T.F. on C.F.F. as reported by different investigators. 1, Cobb, P. W. *J. Opt. Soc. Amer.*, **24**, 107 (1934); 2 and 3, Crozier, W. J. and Wolf, E., *J. Gen. Physiol.*, **24**, 505 (1941); 4 and 5, Bartley, S. H., *J. Exp. Psych.*, 21, 678 (1937); 6 and 8, Ives, H. E., *J. Opt. Soc. Amer.*, **6**, 254 (1922); 7, Porter, T. C., *Proc. Roy. Soc. A*, **70**, 313 (1902); 9, Pieron, H., *C. Rend. Soc. Biol.*, **99**, 398 (1928).

It should be noted that curve 9 is not entirely accurate. Pieron gives no percentage light per cycle (L.T.F.) but percentage dark per cycle. With L.T.F. as co-ordinate the curve should be reversed. It is, in fact, entirely compatible with curves 8, 3, 2, for example

a steady light of such an intensity that for all the L.T.F.'s we used the I_M was equal to that of the 0·9 L.T.F. As we expected, this resulted in complementary L.T.F.s having the same C.F.F. no matter what the shape of the uncompensated curve. A selection of our results is shown in Fig. 2. It adds to our satisfaction that in those cases where the uncompensated curves are symmetrical, our compensation has no effect and the curves remain symmetrical.

The bow-shaped symmetrical curve is also to be expected from the Fourier analysis. If one assumes (as one very plausibly may near the C.F.F.) that only the first flickering component of the Fourier analysis is effective, then one would expect the relationship of C.F.F. to L.T.F. to follow the relationship between the amplitude of the first flickering component and the L.T.F. This latter is, in fact, a simple bow-shaped curve with a maximum at 0·5 L.T.F.

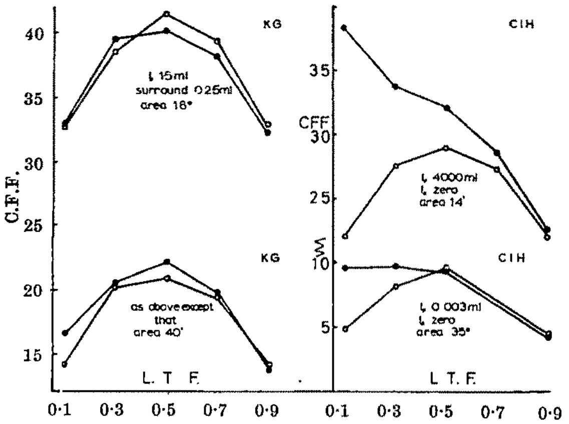

Fig. 2. The effect of changing the light-time-fraction on the critical flicker frequency. Filled circles represent mean C.F.F. with L.T.F. uncompensated for mean intensity. Empty circles represent mean C.F.F. with L.T.F. compensated so that the mean intensity is that of the uncompensated 0·9 L.T.F. This was done by adding a steady light to the remaining L.T.F. stimuli

We have already mentioned that the degree of asymmetry of the uncompensated curve should be predictable if one knew the relationship between I_M and C.F.F. for a given I_F. Complete data on this do not exist, but a very plausible deduction can be made from the very extensive data on the relationship between I_M and C.F.F. when I_F varies with I_M keeping I_F/I_M constant. This is, in fact, the usual way in which the relationship between C.F.F. and stimulus intensity has been obtained, using square waves of variable intensity with no background. Typically C.F.F. increases linearly with log I except for two regions where intensity has little or no effect on C.F.F.; see, for example, Hecht and Smith[7]. The first of these occurs at about 0·001 ml. between the photopic and scotopic regions, the second occurs at very high intensities, about 1,000 ml., where the direction of the relationship may actually reverse. Between these two regions C.F.F. increases markedly with intensity. In the two regions where intensity has little influence on C.F.F., the effect of I_F in increasing the C.F.F. and of I_M in decreasing it must almost exactly balance. In between, the effect of I_F is relatively greater. If we assume that this is because I_M is having a smaller effect in the intermediate region, then we would expect the least degree of asymmetry in the C.F.F.–L.T.F. curves under this condition. The two curves on the left-hand side of Fig. 2 were, in fact, obtained in this region, and the slight effect of area which they show fits the greater effect of increasing intensity for the larger areas. The two regions where intensity has little effect on C.F.F. would be expected to produce the greatest degree of asymmetry since here we have supposed that I_M will be exerting its greatest effect and the asymmetry is due to the change of I_M with L.T.F. in the uncompensated condition. The two curves on the right of Fig. 2 were obtained under these conditions.

There remains the possibility that the regions in which intensity has little effect on C.F.F. are due not to a change in the effectiveness of I_M but to a change in the effectiveness of I_F. However, de Lange[8] has published enough data to make this seem extremely unlikely although his data do not quite cover the necessary intensity range. The present experiments, of course, show that at 0·001 ml. and at 1,000 ml. I_M has a considerable influence on C.F.F., while at 1·5 ml. it has almost no effect.

The application of Fourier analysis to physical systems with a limited frequency response is strictly possible only for linear systems. There is a great deal of evidence that the eye, like most other sense organs, is non-linear in its response. However, there are many non-linear systems where the analysis of square wave impulses can give useful information provided not too much is expected of it. In the present case we have made only the most elementary use of the concepts of Fourier analysis. How far the method can be extended remains to be seen.

We wish to thank the Director-General of Medical Services for permission to publish this paper.

LETTERS TO THE EDITORS

RADIOPHYSICS

Some Preliminary Experimental Tests of a Novel Method of Radiating at Very Low Frequencies

For some years the idea of using an island as a radiator of very low frequencies (VLF) has been discussed in this Establishment. A long, narrow island some 20 miles by 1 mile, composed of poorly conducting material, would be ideal for the purpose. A narrow peninsula would provide a somewhat less efficient radiator. There are some similarities with the slot aerial, but the analogy cannot be pressed too far.

Experiments have recently been carried out using a peninsula some 10 miles long. A cable was laid across its root and the ends of the cable earthed in the sea. Power was fed into the mid-point of the cable.

If it is assumed that the island or peninsula is sufficiently narrow for the far-field to be determined by the algebraic sum of the currents on either side of it, then for radiation purposes a standing wave pattern of a half-wave dipole, or a correctly phased series of them, could be produced. Sufficiently low lobes might then be expected from a large enough array to launch very low-frequency waves at an angle suitable for long-range propagation. In the present trials it is quite probable that the major part of the radiation passed well above the receiving sites investigated, and returned to earth at much greater ranges.

Of several sites considered for the preliminary work, the Loch Long/Gareloch area offered the most advantages. Fig. 1 shows the position of the earthing plates $P1$ and $P2$. The earthing plates consisted of thin copper sheets 6 ft. × 3 ft., mounted on wooden frameworks. Three such plates spaced about 50 yards apart were used in each Loch. They were suspended near the surface with the aid of a system of buoys. The cable used was ordinary power cable of which approximately 3,000 yards were laid.

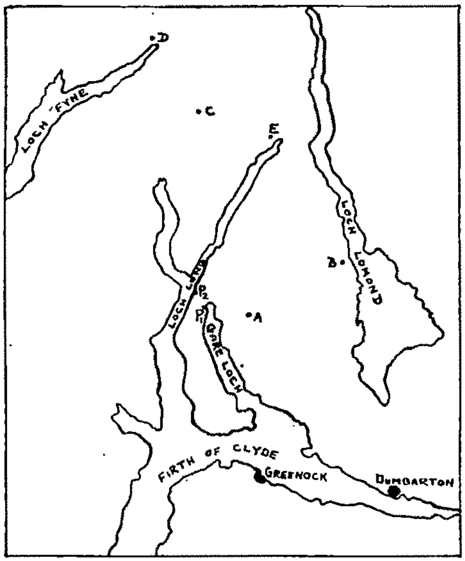

Fig. 1. Trials area

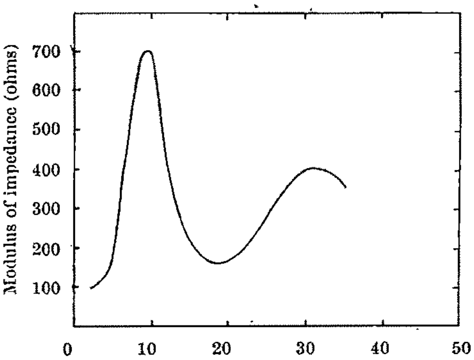

Fig. 2. Total path-impedance at high water

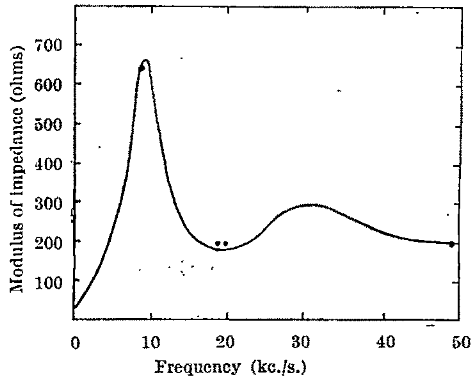

Fig. 3. Total path-impedance. ——, between high and low water ; ●, at low water

The transmitter delivered 50 watts at a frequency of 10 kc./s. The signals were received on a standard communications receiver with a high-Q ferrite loop aerial.

The objects of the initial experiments were to determine the suitability of such a peninsula for a radiator of very low frequencies and to determine its impedance characteristics.

Although the atmospheric noise appeared to be abnormally high, the signal was received at points A, B, C, D and E, shown in Fig. 1. At these points the receiving loop aerial could be used to obtain the approximate bearing of the transmitting aerial, and in each case this bearing appeared to point towards the centre of the sea-path. This was true, even at point A, when the receiving loop plane was rotated about a vertical axis: however, at A, reception was also achieved with the plane of the loop horizontal, which was not the case elsewhere.

It was expected that when the total length of current-path was an odd number of half wave-lengths the impedance would be high, whereas when the path-length was an even number of half wave-lengths the impedance would be low. Impedance minima were therefore expected, due allowance being made for the measured path-length, at integral multiples of 10 kc./s. and impedance maxima at odd integral multiples of 5 kc./s. As shown in Figs. 2 and 3, a maximum occurred at 10 kc./s. and a minimum at 20 kc./s. From subsequent experiments it appears that the effect arises on account of changes in the characteristics of the cable due to the proximity of the ground with which it was in contact.

It is concluded that the experiments clearly demonstrate the feasibility of the present proposals, as genuine radiation effects were observed. Some attention must, however, be paid to reducing the cable capacity to earth and the associated losses.

In conclusion, it should be mentioned that during these first trials, Press reports appeared of a similar investigation in Antarctica which had a rather different objective.

Thanks are due to Messrs. R. Benjamin, A. T. Rawles and K. V. Watt, of this Establishment, for useful discussions, to Messrs. W. R. Carter, W. L. Hibbens and E. G. Richards for assistance in the trials, and to the Admiralty for permission to publish the results.

ASTROPHYSICS

Minimum Range to Artificial Earth Satellites

A prerequisite for ionospheric work with satellites by means of the Doppler method is the knowledge of the behaviour of the Doppler-frequency shift in free space. A free-space condition prevails, if the operating frequency f is much greater than the maximum plasma frequency. It is the purpose of this communication to present in a general form an equation from which the minimum range between a satellite S and an observer P can be determined and to illustrate the magnitudes of higher-order terms.

The first reports which appeared in the technical literature regarding the minimum-range equation generously neglected the effects of the curvature of the satellite orbit. An equation which included the effects of this curvature has been reported[1]. Specific reference to the previous neglect has been made by Brito[2] and in a simplified form by me[3]. Priester and Brito took into account the relative velocity between source and observer, but neither equation was complete. To arrive at a complete expression for the minimum-range equation, I shall first consider a two-dimensional case with the observer at rest ($v_p = 0$) in the plane of the orbit of S. In this case, one obtains the following equation for the time-derivative of the Doppler-shift curve for $v_s/c \ll 1$:

$$\lambda \dot{f}' = -\frac{v_s^2}{R}\sin^2\psi + \frac{v_s^2}{\rho_s}\cos\alpha \qquad (1)$$

where $\lambda = c/f$, c is the velocity of light in free space and f is the transmitter frequency of the satellite, $\dot{f}'$ is the time derivative of the frequency f' received at P, v_s is the orbital speed, R is the range SP, ρ_s is the radius of the orbit of S, $\psi = \sphericalangle \vec{v}_s \vec{R}$, and $\alpha = (\pi/2 - \psi)$. In the limit equation (1) assumes the form (when $\psi = \pi/2$, $\alpha = 0$, $R = R_m$):

$$\lambda(\dot{f}')_{\text{max.}} = -\frac{v_s^2}{R_m} + \frac{v_s^2}{\rho_s} \qquad (2)$$

or

$$\lambda(\dot{f}')_{\text{max.}} = -\frac{v_s^2}{R_m} + \frac{v_s^2}{\rho_s}\cos\xi \qquad (3)$$

if P is outside the plane of the orbit[4], ξ is the angle between $\vec{\rho}_s$ and $\vec{R}_m$ and R_m is the minimum range between S and P. In equations (1), (2) and (3) the second terms on the right represent the components of a radial acceleration toward P.

An earth-based observer at P, who is not located at the poles, is in orbital motion ($v_p \neq 0$) due to the spin of the Earth around its axis. Consequently, the minimum-range equation contains an additional radial acceleration component and can be written as:

$$\lambda(\dot{f}')_{f'=f} = -\frac{v^2_{\text{rel.}}}{R_m} + \frac{v_s^2}{\rho_s}\cos\alpha - \frac{v_p^2}{\rho_p}\cos\beta \qquad (4)$$

where

$$v_{\text{rel.}}^2 \doteq v_s^2 + v_p^2 - 2v_s v_p \cos j,\ j = \sphericalangle \vec{v}_s \vec{v}_p,$$
$$\alpha = \sphericalangle \vec{\rho}_s \vec{R}_m,\ \beta = \sphericalangle \vec{\rho}_p \vec{R}_m$$

with the signs in (4) corresponding to $\alpha, \beta < \pi/2$. It is seen that $\lambda(\dot{f}')_{f'=f}$ which may be different from $\lambda(\dot{f}')_{\text{max.}}$ is equal to the sum of three accelerations. The first term represents the radial acceleration due to a rotation of S with $\vec{v}_{\text{rel.}}$ perpendicular to $\vec{R}_m$. Since R increases for any displacement from $R = R_m$, the sign of the first term is negative. The second and third term represent the components of a radial acceleration for the satellite (v^2_s/ρ_s) and for the observer (v^2_p/ρ_p) in the direction of $\vec{R}_m$.

For $\rho_s = \rho_s = \infty$, including now the relativistic correction, one obtains the minimum-range equation for linear orbits:

$$\frac{\lambda(\dot{f}')_{f'=f}}{\sqrt{1-\left(\frac{v_{\text{rel.}}}{c}\right)^2}} = -\frac{v_{\text{rel.}}^2}{R_m} \qquad (5)$$

For satellite orbits the relativistic correction amounts to about four parts in 10^{10}. For practical purposes equation (4) seems adequate, since this correction corresponds to a quality of measurement equivalent of resolving less than 1 mm. of a 1,000-km. range.

The orbital motion of S and P may not be circular. Moreover, since the Earth is moving around the Sun ($v_G \doteq 30$ km./sec.) and since the Sun is moving in a curved orbit ($v_H \doteq 230$ km./sec.) around a centre of curvature, and since our Galaxy may move in its own curved path, etc., one can, for theoretical completeness, write the minimum-range equation in a form which includes all possible velocity and acceleration components. For $v_{\text{rel.}} \ll c$ this leads to the scalar equation :

$$\lambda(\dot{f}')_{f'=f} = -\frac{v_{\text{rel.}}^2}{R_m} + \sum_i\left(\frac{v_{is}^2}{\rho_{is}}\cos\alpha_i - \frac{v_{ip}^2}{\rho_{ip}}\cos\beta_i\right) + \sum_i(\dot{v}_{is}\cos\gamma_i - \dot{v}_{ip}\cos\delta_i) \qquad (6)$$

where in vector form, $\vec{v}_{\text{rel.}} = \sum_i(\vec{v}_{is} - \vec{v}_{ip})$ and the signs in equation (6) correspond to $\alpha_i, \beta_i, \gamma_i, \delta_i < \pi/2$. i is an index which refers the motion of S (satellite) and P (observer) to centres of curvature in the systems of the Earth, Sun, Galaxy, etc., respectively. In equation (6) both summations contain components of radial and tangential accelerations in the direction of $\vec{R}_m$.

Since the magnitudes of the higher-order terms (Sun, Galaxy, etc.) are less than 10^{-9} times the first term in equation (6) the slope of the Doppler-shift curve can be said to contain detectable and 'undetectable' elements of motion. The cause of the 'undetectable' motions reaches deep into space. For the detectable motions equation (4) seems sufficient. An estimate of the significance of each component of (4) reveals that for S and P orbiting, for example, in the equatorial plane with S at 1,000 km. elevation, the error introduced in R_m by neglecting the curvature of the orbit of S is about -15 per cent, while the error introduced by neglecting the curvature of the orbit of P is about $+0 \cdot 1$ per cent. If the slope of the Doppler-shift curve can be measured to an accuracy better than about 0·1 per cent, the latter contribution cannot be neglected. This does not mean, however, that with less accuracy the contribution due to the radial acceleration of P vanishes. If P is located at either pole of the Earth, $v_p = 0$ and equation (3) is valid for P outside the plane of the orbit of S.

PHYSICS

Confining a Plasma in Steady Electric and Magnetic Fields

I HAVE suggested that ions may be trapped in an electric potential-well situated in a magnetic field[1]. The basic field configuration proposed was analogous to that in the Penning or Philips ion gauge discharge[2], where electrons are trapped, say, between two cathodes for a comparatively long period before they reach the anode ring situated between the cathodes. For trapping ions, the required potential-well is produced, for example, if a cathode ring is situated between two anode plates, with a magnetic field parallel to the axis of the cathode.

Experimental work was undertaken to study this possibility. The main experimental difficulty in realizing a field configuration suitable for confining ons was due to the fact that ions had to be generated by auxiliary discharges in regions adjacent to, but different from, the trapping region and had to be drawn into the latter region. In the case of Penning discharge, the electron current is initiated in the trapping region itself by field emission from the cathode or by ionization produced by cosmic or other background radiation.

Deuterium was used in these experiments, because the neutrons emitted by D–D reactions served as the indicator for the study of the plasma produced. Recent experiments were carried out at a gas pressure of a few microns of mercury. The voltage used for the discharge varied from 10 to 20 kV., and the discharge current was 5–10 m.amp. The magnetic field available was about 1,700 gauss.

Three main results were obtained as a result of this work: (*a*) The emission of neutrons indicated that high-energy ions were produced in this discharge. (*b*) By scanning the region of the discharge with a neutron detector provided with neutron collimation, it was found that the neutrons were mainly from the discharge region and not from the electrodes. (*c*) The most important result was that there was evidence for confinement of the ions. Because of the uncertainty in estimating the ionic component of the discharge current and the effective ion density, an estimate of absolute efficiency of neutron production was only of dubious value at the present stage of the experiment. Therefore, comparative neutron yields at different voltages were determined, with other parameters kept constant. If there were no confinement of the ions one would expect that the relative yield should follow the theoretical Gamow curve which has been experimentally verified[3-5]. On the other hand, if there were any confinement, the lower-energy ions would be confined relatively more than the higher energy ions, even in this very limited magnetic field. This meant that a graph of neutron yield at different voltages, when normalized at a particular energy on the Gamow curve, should show relatively larger yield at lower energies. Indeed, this was observed (Fig. 1). The solid line shows the variation of D–D reaction cross-section with energy[3], and the dashed line represents the relative yield of neutrons in the present experiments, at different voltages, normalized at 16 kV.

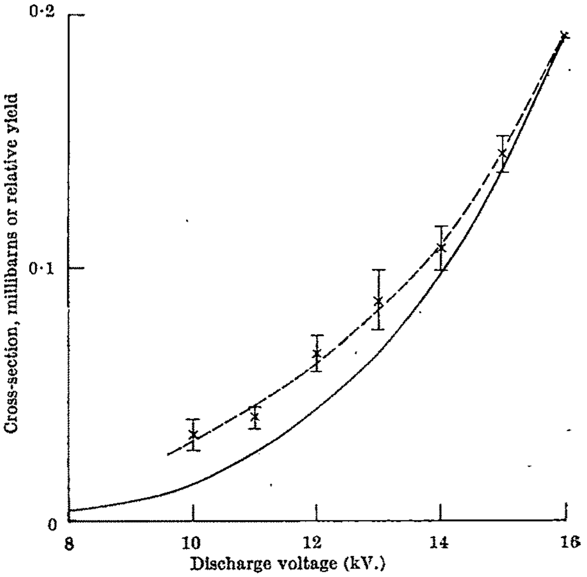

Fig. 1

Work is being continued, and the experimental details will be published elsewhere.

I am grateful to my colleagues Mr. S. S. Samant for assistance in the experimental work, Mr. M. L. Uplekar for the construction of some equipment, and Dr. A. P. Thatte and Mr. S. S. Bhave for useful discussions. I thank Prof. D. Y. Phadke for his encouragement.

A Proposal for increasing the Beam Output from a Synchrocyclotron

In this communication, the possibility is considered of appreciably increasing the mean output of a synchrocyclotron, using relatively inexpensive equipment and with the expenditure of only a small amount of electrical power.

Suppose that a small dee system, covering the orbits of ions with energies of up to about 5 MeV., is placed opposite the live dee at the centre of the machine. To this small additional dee a high-voltage radio-frequency signal is fed which is in antiphase to that on the main dee. This signal is derived from the main oscillator system after amplification in a separate power amplifier. The auxiliary amplifier is pulsed on at a time slightly before the main dee commences to capture ions from the ion source, and is switched off when the captured ions have gained on the average a few MeV., that is, when the ion bunch is circulating at a radius such that it truly enters the main dee electrode and thus picks up the full dee voltage. It is essential that the auxiliary dee signal is reduced to a very small value as the ion bunch approaches the radius of the small dee edge, to avoid inducing radial betatron oscillations.

In Fig. 1 the assumed variation of the energy gained per turn by an ion is shown as a function of the orbit radius. Three cases are shown: the first curve corresponds to a normal synchrocyclotron, and the second curve to a machine modified in the way here described. The third curve, produced by too large a voltage on the small dee, is probably undesirable, because ions captured into stable orbits at the peak of the curve would afterwards be lost. Obviously, to achieve the required shape of the curve, the auxiliary power amplifier output must be gradually tapered off.

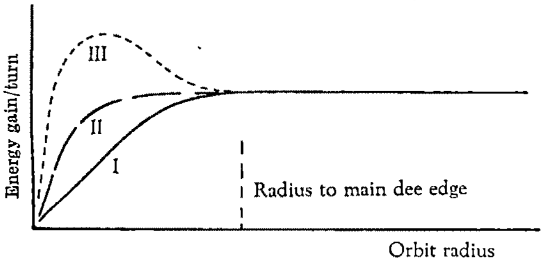

Fig. 1

The manner in which such an arrangement could produce an increase in the intensity of the beam is now considered. First, the energy gained per turn by the ions would be increased, permitting the use of a larger area in phase-space for ion capture. Secondly, the ions would be extracted more rapidly from the region of high particle density near the ion source, with a consequent reduction in the number of ions lost by gas scattering. Thirdly, the production of a more uniform electric field in the central region would cause a reduction in the movements of the centres of the orbits away from the centre of the machine, thereby reducing the amplitudes of the radial betatron oscillations.

The band-width and power requirements of the auxiliary amplifier are quite modest; a power of 1–2 per cent of the main oscillator power is sufficient, and the band-width need only cover the range of synchronous frequencies required by the ion bunch in its passage from the source to the radius at which the auxiliary amplifier is switched off. So that large signals are not induced in the small dee system by the main dee when it is switched off, the feed line should be resistively loaded; but this is usually also required to achieve a sufficiently wide band-width. In addition, a small earthed screen between the main dee and the auxiliary dee is desirable to reduce the electric coupling between the two dees and to improve the shape of the field near the centre of the machine. A typical arrangement is shown in Fig. 2.

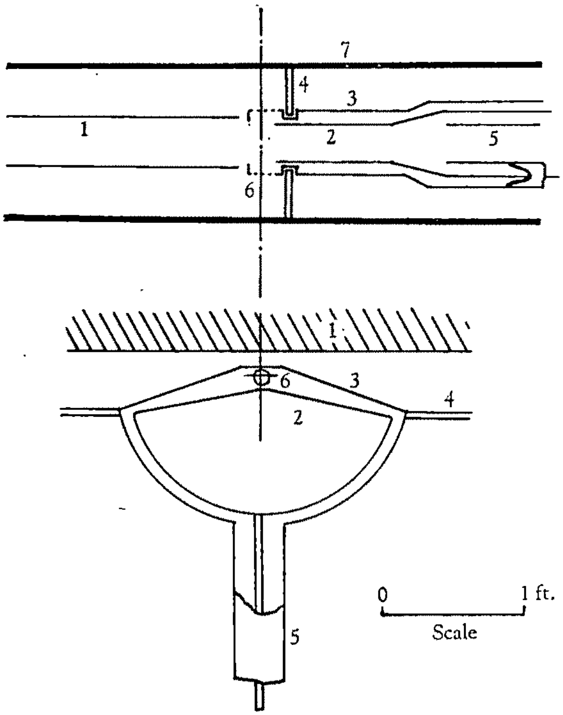

Fig. 2. 1, Main dee; 2, auxiliary dee; 3, auxiliary screen; 4, dummy dee; 5, co-axial feeders; 6, hole for ions; 7, vacuum chamber walls

Preliminary tests of this scheme have been made with the Harwell 110-in. synchrocyclotron, using an 11-in. radius dee with a total operating time of approximately 50 μsec. in each main modulation cycle. The rate of repetition for this machine is 200 c./s. A peak voltage of 4 kV. was used on the small dee, the main dee voltage being approximately 8 kV. peak. Despite a reduction in the vertical aperture of 25 per cent, caused by the small dees, an increase in the beam current measured at 50 meV. of approximately 60 per cent was readily achieved.

I thank the members of the team engaged on this work, in particular P. S. Rogers, for their help, and also J. D. Lawson for helpful discussions.

Effect of a Resisting Couple on the Rotational Motion of a Rigid Body

In a recent communication[1], Nonweiler demonstrates the proposition that an external couple applied to a rigid body about its instantaneous axis of rotation in the sense opposing its rotation tends to cause the axis to approach the axis of greatest moment (provided that the instantaneous axis is not initially that of a permanent rotation). He refers to the rotational motion of artificial Earth satellites and the manner in which their instantaneous axes of rotation have been observed to approach the axis of greatest moment and suggests that this theorem may be relevant.

It seems to me, however, that if the underlying assumption of Nonweiler's proposition, that the external couple $\mathbf{G}$ is opposite to the angular velocity vector $\mathbf{w}$, is interpreted in the usual sense, $\mathbf{G} = -k\mathbf{w}$ (k, positive), then it does not, in general, apply to bodies under the influence of aerodynamic damping moments. In most practical cases, we are concerned with bodies having axial symmetry, and the damping moment about the axis of symmetry will be quite small compared with the damping moment about a lateral axis; in other words, the spin will tend to be retained whereas angular motions in pitch and yaw will be damped. Thus, whereas the direction of $\mathbf{G}$ will be such that $\mathbf{G}.\mathbf{w}$ is negative, the more restrictive condition $\mathbf{G} = -k\mathbf{w}$ will not apply. The only case to which the theorem as stated is directly applicable is that of a body, such as a sphere, having inertial asymmetry, but equal damping derivatives about three orthogonal axes.

Nonweiler derives the equation:

$$\frac{d}{dt}(h^2/2T) = \tfrac{1}{2}(\mathbf{G} \times \mathbf{h}).(\mathbf{h} \times \mathbf{w})/T^2 \qquad (1)$$

where $\mathbf{h}$ is the vector moment of momentum and T the kinetic energy of rotation. He shows that an increasing value of $(h^2/2T)$ may be interpreted as a movement of the instantaneous axis of rotation towards the axis of greatest moment. Now the term $(\mathbf{G} \times \mathbf{h}).(\mathbf{h} \times \mathbf{w})$ is positive if, and only if, the component of $\mathbf{G}$ in the plane of $\mathbf{w}$ and $\mathbf{h}$ is directed towards the side of the line of action of $\mathbf{h}$ opposite to $\mathbf{w}$. This includes the particular case $\mathbf{G} = -k\mathbf{w}$, but does not include the more general condition that $\mathbf{G}.\mathbf{w}$ is negative, satisfied, in practice, by an aerodynamic resisting couple. For this latter case, the conclusion may be rather different. Instead of the instantaneous axis of rotation tending to approach the axis of greatest moment, it will in most practical cases tend to approach the axis of symmetry, whether this is the axis of greatest moment or not. For example, a long pencil-like object spinning about its axis of symmetry and subjected to a resisting couple would be stable and not unstable as Nonweiler's proposition might imply. The fact that the converse behaviour has been observed on artificial Earth satellites would suggest that they are not in fact behaving as rigid bodies and that the role of internal energy dissipation is a dominant one.

The result for this more general condition may best be seen by resolving the vectors along principal body axes. Thus, writing:

$$\mathbf{w} \equiv (p,q,r)$$

$$\mathbf{G} \equiv (-\lambda p, -\mu q, -\nu r)$$

equation (1) becomes:

$$\frac{d}{dt}(h^2/2T) = \Sigma q^2 r^2 (\nu B - \mu C)(B - C)/T^2 \qquad (2)$$

where (A, B, C) are the principal moments of inertia and the summation is taken over all three components.

This equation could be used to indicate the motion of the instantaneous axis of rotation in any particular case, but no general interpretation can be given. However, for an axisymmetric body, we may put $\nu = \mu$, $C = B$ and equation (2) reduces to:

$$\frac{d}{dt}(h^2/2T) = p^2(q^2 + r^2)(\mu A - \lambda B)(A - B) \qquad (3)$$

In most practical cases, μ will be large compared with λ so that $(\mu A - \lambda B)$ will be positive. The sign of $\frac{d}{dt}(h^2/2T)$ will then be determined by that of $(A - B)$. Thus for $A > B$, $h^2/2T$ will increase and the instantaneous axis of rotation will tend towards the axis of greatest moment, that is, the x axis, which is the axis of symmetry. If $A < B$, $h^2/2T$ will decrease and the axis of rotation will tend towards the axis of least moment, that is, again towards the x axis. Thus it will always move towards the axis of symmetry provided that the condition $\mu A > \lambda B$ is satisfied.

Anomalous Thermoelectric Properties of Gadolinium Selenide

AN earlier paper[1] has shown a narrow range of composition in the gadolinium–selenium system to exhibit highly interesting thermoelectric figures of merit ($Z = 4{\cdot}5 - 6{\cdot}0 \times 10^{-3}$ at 800° C.) The composition attaining such values lies between the two compounds GdSe and Gd_2Se_3, the characteristics of which have been summarized[2] as follows:

GdSe: NaCl type structure, bonding essentially covalent, very low electrical resistivity, Seebeck coefficient ~ 10 μV./deg. C.

Gd_2Se_3: defect Th_3P_4 type structure, bonding essentially ionic, very high electrical resistivity, Seebeck coefficient ~ 300 μV./deg. C.

High thermoelectric figures of merit are obtained when the preferred composition (~ 90 per cent Gd_2Se_3) has been quenched from temperatures just above the melting point (~ 1,800° C.), but these are lost on remelting or slow cooling from the melt. The parameters (Fig. 1) from which Z is calculated in the preferred composition present several interrelationships which are anomalous in the light of normal thermoelectric semi-conductor theory[3]. A detailed paper, to be submitted elsewhere, attempts to correlate and explain these anomalies.

Examples of the anomalies in the gadolinium–selenium composition are as follows: the increase in Q values with temperature suggests that the material is impurity-degenerate; but this does not conform with the linear or slightly decreasing values of $\varkappa$ which indicate non-degeneracy. The normal comparison between ZT and Q^2/L is not found. Up to ~ 800° C., $\varkappa_{ph}$ is proportional to reciprocal temperature, but above this the relationship $\varkappa = \varkappa_{el} + \varkappa_{ph}$ obviously does not apply. Derivation of $\varkappa_{el}$ from ρ values through the Wiedemann–Franz relationship is inadmissible, because the system is heterogeneous, as indicated by a plot of ρ vs. T. Normal X-ray diffractometry and metallography show, however, the material to be essentially single phase, and indeed when two phases are obviously present the material loses its high Z values.

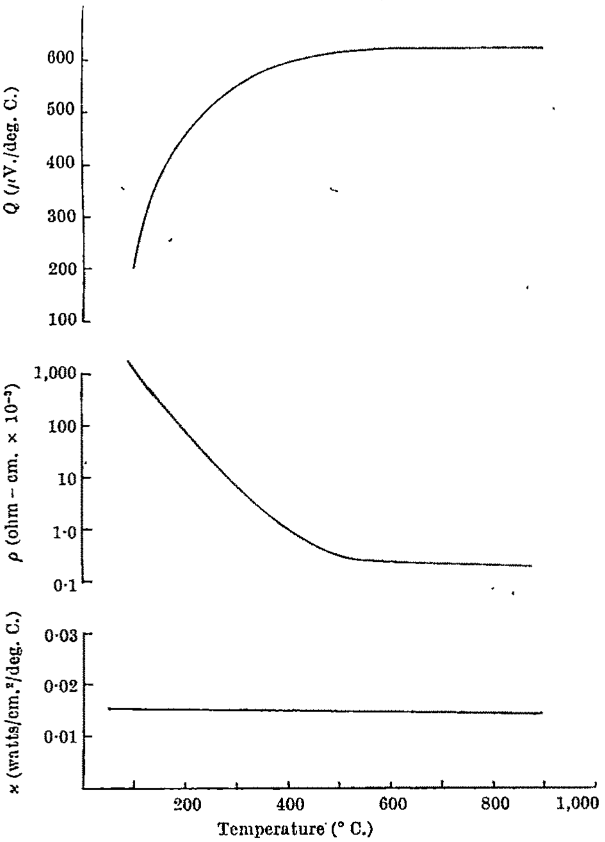

Fig. 1

Duwez *et al.*[4] have recently shown that, under conditions of rapid quenching from high temperatures, metastable and previously unknown intermetallic compounds are found in alloy systems. Similar work has been reported by Russian workers and summarized by Yevseyev[5]. In the present system, it is now believed that, under appropriate conditions of preparation, GdSe and Gd_2Se_3 interact to form such a metastable compound. This metastable product is believed to involve a lattice interaction through which the covalently bound GdSe and the ionically bound Gd_2Se_3 share a common crystal plane boundary. The bonding across such a boundary must be visualized as existing in a highly resonant condition; preliminary calculations suggest a room temperature resonance frequency of $\sim 4 \cdot 6 \times 10^{17}$ sec.$^{-1}$.

The essentially ionic nature of the predominant Gd_2Se_3 component, and the presence of the bounding plane postulated can be expected to present some resistance to the passage of carriers of electrically stimulated charge unless a novel transport mechanism is involved. This we now feel can be rationalized, on the basis of the phenomenon observed, by visualizing electromagnetic waves of thermal frequency—'thermons'—as charge carriers, and these associated with an almost purely inverse temperature-dependent variation in frequency of bonding resonance. Consequently, 'thermons' of a given frequency will not penetrate the resonance barrier until, by thermal vibration, the resonance frequency has decreased to the point at which the incident wave and the resonance oscillation are in harmony. At this point 'thermons', carrying the electrical charge, will avalanche through the barrier and electrical resistivity will drop.

Considering further the function of thermons in terms of Seebeck coefficient, we can visualize their passage through the resonating barrier in terms of oscillator-wave interaction theory, from which it is expected that energy will flow to or from the incident thermons, depending on resonance or otherwise of the bonding frequency (oscillator) and the incident frequency (wave). We believe, therefore, that the remarkably high Seebeck coefficient of such lattice-interacted gadolinium selenide can be attributed to the acquisition by incident thermons of energy from this resonating boundary which is then translated into terms of e.m.f. The behaviour thus presented is similar to that which forms the basis of 'maser' operation and, carrying the concept further on the basis of our most recent work, we believe that, by suitable selection of crystal parameters, materials and temperatures, it is possible so to adjust the resonating boundary frequency that translation from any one electromagnetic frequency into another may be possible.

Structure of Calcium Soap Fibres

PREVIOUS publications on soap particles have contained conflicting views and evidence as to the orientation of the hydrocarbon chains within the particles. This is true even for a single soap, calcium stearate, and may be due to different methods of preparation leading to different crystal habits and/or structures.

So far as we are aware, no direct evidence from electron microscopy has yet been published concerning calcium soap fibres. We are particularly interested in materials such as are used in lubricating greases, and the samples we have examined were in fact prepared from calcium-based greases made with commercial grade fatty acid. It must be noted, therefore, that although our fibres contained a high proportion of C_{18} fatty acid, some of this was unsaturated and there were also minor proportions of acids of other chain-lengths present.

The method of sample preparation was the simple one of pressing a microscope grid coated with a carbon film on to a smear of the grease. The grid was then removed, washed in *n*-heptane to remove residual oil from the soap particles transferred, and examined in a high-resolution microscope without further treatment. Care was taken to keep the beam current low and to minimize the time of exposure of the sample to the electron beam.

Two types of soap fibre are commonly found in this type of grease: (i) small so-called 'twisted' fibres of widths about 0·06μ, which actually have more the appearance of helically rolled thin ribbons; (ii) ribbons of variable larger dimensions which have no twist.

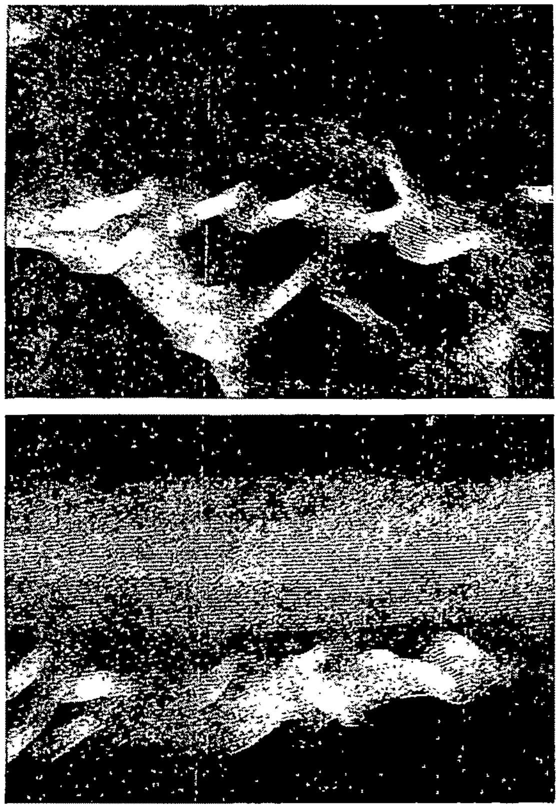

Fig. 1. Electron micrographs of calcium soap fibres showing structural detail (reverse printed for clarity). (× 114,000)

On examining both types at high resolution, striations were seen running parallel to the lengths of the fibres. The spacing of these striations is 42 Å., which, in the absence of an accurate calibration for the microscope, agrees well enough with the long-spacing value of 47·5 Å. derived from X-ray diffraction patterns of the soap. It is concluded that the striations are due to the 'edge on' view of the layers of metal atoms in the soap structure, which thus run approximately parallel to the direction of thickness and lengthwise. Fig. 1 shows the effect in both the straight and 'twisted' types of fibre, and does in fact help to suggest that there may be no marked difference in the structures of the two types. Furthermore, it gives some support for the idea sometimes entertained, that the small 'twisted' fibres result from the splitting up of the larger flat ones. In other micrographs of these grease fibres, edge dislocations have been seen, and traces of moiré fringe effects have been seen in crossed fibres.

Camp and Shuttleworth[1] found somewhat similar detail in sodium laurate fibres produced from aqueous solution, and from it they drew the same conclusions regarding the disposition of the molecules, thus supporting the ideas of Bondi and co-workers[2] on soap fibres generally. They found it necessary, however, to resort to metal shadowing in order to reveal this detail, and they believed that they were seeing agglomerates of shadowing metal nucleating on some unit within the fibre.

It seems likely that not all soaps crystallize in this way. Vold[3], using the same X-ray technique as Bondi, found sodium palmitate to fit in with the older ideas[4], namely, to have its molecular layers arranged perpendicularly to the thickness of the fibre. She claimed indirect evidence that calcium stearate, presumably the monohydrate, also obeyed the older pattern. Stanley[5] carried out some X-ray diffraction work on calcium stearate monohydrate using material re-crystallized from a mixture of propylene glycol and chloroform ; and in the lath-like crystals resulting he also found evidence that this soap crystallized with its molecular layers perpendicular to the direction of thickness.

The fibres with which we are working are formed under very different conditions, and differences of habit and/or structure seem not unreasonable, particularly in view of the impure nature of our material. What is surprising is that the structural detail is more stable and visible in the instrument than might be expected from accounts of other work in electron microscopes on crystalline long-chain compounds. It has not been necessary to resort to metal shadowing as did Camp and Shuttleworth, or to use osmium tetroxide as did Trurnit and Schidlovsky[6] when studying deposited multilayers of soaps. The metal atoms in calcium stearate are, admittedly, heavier than those in sodium laurate ; but they are only half as numerous, and, from simplified considerations of electron scattering power relative to carbon, they are likely to be only about 40 per cent more effective than the sodium atoms. We have noted striations still visible in these untreated calcium soap fibres after exposures of 3½ min. to the beam. The stability may in part explain the visibility.

Supposing that these grease fibres differ only from Stanley's thin crystals in external form, then their stability compared with sodium laurate could be due to a structure different from the bimolecular sheet arrangement widely accepted for soaps of monovalent metals. In his communication Stanley proposed an arrangement of overlapping molecules which might be less easily disrupted. It is noteworthy that such calcium soap fibres seldom show any longitudinal splitting of the type seen, for example, in some sodium soaps.

A comparison of X-ray long spacing values for Stanley's pure calcium stearate (50·3 Å.) and our fibres (47·5 Å.) suggests to us that the two materials may have essentially the same structure. The value for our soap is smaller by an amount roughly in keeping with the probable distribution of chain-length in our raw material. In considering the properties of these fibres we should not, however, overlook the possibility of effects introduced by minor components of the fatty acid mixture employed. Bondi, for example, reported that it was sometimes impossible to produce fibres from pure soaps.

We are continuing and extending these electron microscope investigations on soap fibres in greases, and hope to publish a fuller account in due course. We thank the Directors of "Shell" Research, Ltd., for permission to publish this communication.

CHEMISTRY

Deviations from the Steady-State in Ion Transfer through Perm-selective Membranes

DURING experiments on polarization phenomena of perm-selective membranes, results were obtained which were inconsistent with the generally accepted idea that during the transfer of ions through such membranes by means of a constant direct current, a steady state is established under given experimental conditions[1].

The observation led to a series of rigidly controlled experiments in which I attempted to determine whether in fact a steady state is obtained.

A constant direct current was passed through a homogeneous cation exchange membrane bounded on both sides by 0·01 *N* silver nitrate solution. Silver electrodes were used, and the current obtained from a constant voltage rectifier (max. output : 400 V.) with less than 0·2 per cent ripple. To eliminate current variations a 44-k.ohm resistance was placed in series with the experimental cell. The potential difference through the system was measured by means of saturated calomel electrodes through 0·01 *N* potassium chloride/0·01 *N* potassium nitrate salt bridges, and a calibrated oscilloscope with d.c. amplifier. Measurements were made at various current densities and the current measured by means of an avometer. The solutions were stirred at 1,100 r.p.m. with glass stirrers.

After allowing some time for constant conditions to be established, I found that with the passage of the direct current, an unharmonic oscillation of the potential difference between the two sides of the membrane was obtained, about a constant average value. The maximum spread of the oscillation varied with the current density and at 30 m.amp./cm.^{2} increased to about 500 mV. (Table 1).

A control experiment in which the membrane was left out gave a maximum value at 30 m.amp./cm.^{2} of 20 mV. (Table 1). Further tests repeated with accumulators as the direct-current source gave similar results.

Table 1

Current density (m.amp./cm.^{2})	Spread of oscillation (mV.)		
	0·01 *N* $AgNO_3$	Control experiment	0·01 *N* $AgNO_3$ in agar–agar gel
1·5	5	5	20
3	10	5	100
6	150	10	1,000
15	300	20	8,000
30	500	20	—

In order to limit all other effects except those caused by current and diffusion, an additional experiment was made in which the solution in the cell was replaced by an agar–agar gel of the same ionic concentration. In this case, the oscillation spread was much wider and gave a value of 8,000 mV. at 15 m.amp./cm.^{3} At higher current densities the overall voltage increased to such an extent that no constant current could be obtained (see Table 1).

Experiments with an anionic exchange membrane in 0·01 *N* potassium chloride gave similar results.

Since, for steady-state conditions, the potential difference between two points in the system must be constant by definition, the experiments seem to indicate that during ion transport through perm-selective membranes by means of a constant direct current, steady-state conditions need not generally appear. I feel that it is necessary, therefore, to examine anew current theories on such transfer processes, and investigations in this direction are now being undertaken.

I am indebted to Mr. Y. Mahler, of the Electronics Laboratory for his co-operation in the planning and setting up of the measurements.

A New Calcium Magnesiosilicate

A DETAILED investigation is in progress of high-temperature phase equilibria in the system $2CaO,SiO_2 - 3CaO,MgO,2SiO_2$ mainly by special methods of high-temperature microscopy[1,2] and X-ray analysis[3]. A new compound has been located of the approximate molar composition $(2CaO,SiO_2)_{5\cdot 6}(3CaO,MgO,2SiO_2)_{4\cdot 4}$ characterized by the X-ray diffraction pattern given in Table 1. This composition was prepared from crushed quartz (99·95 per cent pure), calcium carbonate (99·9 per cent pure), and magnesium oxide (99·9 per cent pure), by ignition at 1,250° C. in platinum boats in a platinum/rhodium resistance furnace. The fineness of the reaction mixture during ignition is of critical importance to the formation of the new compound. During a heat-treatment of 10 days duration the mixture was ground every two days to pass a 300-mesh sieve. Failure to grind to at least such fineness led to the formation of mainly $\gamma 2CaO,SiO_2$ and $3CaO,MgO,2SiO_2$ with only a small proportion of the new phase.

The X-ray powder measurements were obtained at room temperature in a Guinier-type focusing camera, 114 mm. diameter with copper-$K\alpha$ radiation. Relative intensities (*I*) were estimated visually on an arbitrary scale from 1 (very weak) to 10 (very strong). The density of the new compound is 3·30 and the optical properties are as follows : biaxial positive $2V$ medium (approximately 30°), RI_{Na} $\alpha = 1{\cdot}711$, $\gamma = 1{\cdot}725$.

The phase is formed by solid-state reaction and does not melt congruently.

Sharp, Johnson and Andrews[4] report a new phase, *T*, the presence of which was detected in basic arc

furnace slags. The lines in Johnson's X-ray patterns (private communication), which he considers to be due to a new phase, seem to accord with the strongest lines found in the pattern reported here. The stable phase assemblages between the new compound and adjoining compounds are being studied. It is already clear, however, that over a wide range of composition between $2CaO,SiO_2$ and $3CaO,MgO,2SiO_2$ the X-ray pattern of the new phase is unaltered, supporting the view that the phase is a singular compound and not a member of a solid-solution series.

Use of Krypton for Surface Area Measurements

WE have recently discussed[1] some criteria for the applicability of various gases in measuring the surface areas of solids by the Brunauer–Emmett–Teller[2] method. We concluded that the use of krypton in this technique led to valid and useful results and that previous criticism of the use of this gas was unfounded. However, Thomas[3] has again suggested that 'anomalous' Brunauer–Emmett–Teller plots obtained from krypton adsorption measurements render the use of this gas undesirable. He proposes that the occurrence of phase-changes in the adsorbed film, evidenced by discontinuities in the adsorption isotherm, are associated with these 'anomalous' (and presumably suspect) results.

We wish to re-emphasize the fact that an evaluation of monolayer coverage must be based on the behaviour of the adsorbed film when the first monolayer is nearly complete. Two-dimensional condensation or other transitions in the adsorbed film at lower or higher coverages do not appear to affect the validity of the surface areas evaluated from linear Brunauer–Emmett–Teller plots in the monolayer region. McDermot and Lawton[4], for example, were able to evaluate the surface area of a graphite sample from krypton-adsorption data even though they observed two discontinuities in the isotherm at 77° K. The work of Roberts[5] strongly suggests that krypton adsorbed on an evaporated iron film can be considered a two-dimensional liquid at coverages greater than about 80 per cent of the first monolayer. The energetic considerations which we have previously used[1] are therefore applicable, and valid surface area measurements are obtained in these cases.

We submit, therefore, that the non-linear parts of the plots described by Thomas are irrelevant to the purposes of surface area measurement. The application of the self-consistency criterion[1,6]:

$$p/p_0|_{v_m} = \frac{1}{1 + \sqrt{c}}$$

suggests, however, that if his measurements had been carried to somewhat higher pressures, Thomas would have obtained valid v_m values.

It must be remembered that the useful linear range of a Brunauer–Emmett–Teller plot varies, in terms of relative pressure, with the nature of the solid surface, as we have already shown[1].

Properties of Polyadenylic Acid in Methanol Solution

UNTIL recent years, methanol and ethanol were universally regarded only as precipitants for nucleic acids. However, Geiduschek and Holtzer[1], and later Coates and Jordan[2], showed that at sufficiently low ionic strengths both the above lose their precipitating capacity for deoxyribonucleic acid (DNA) and in fact becomes fairly good solvents, depending upon the concentration of electrolyte.

The above authors have also observed a profound alteration of the over-all macromolecular properties of DNA in the above media, including a drastic fall in intrinsic viscosity and rise in frictional coefficient without any important change in molecular weight. The extensive molecular collapse indicated by the above was largely reversed on replacement of alcohol by dialysis versus water, suggesting that irreversible 'denaturation' in the classical sense had not occurred in this instance.

The present investigation deals with the properties of polyriboadenylic acid (poly A) dissolved in anhydrous methanol. Such criteria as ultra-violet hypochromism and optical rotation have been interpreted as indicating that the alkaline form of poly A in aqueous solution possesses varying degrees of helical content, depending on conditions, and displays in fact many of the characteristics of an intermittently helical system, being rather analogous to ribonucleic acid[3,4].

Solutions of poly A (1 per cent) in water were dialysed exhaustively versus anhydrous methanol according to the procedure of Geiduschek[1]. (The poly A used was prepared by the action of the polynucleotide phosphorylase of *M. lysodeikticus* (supplied by Dr. R. Beere) upon adenosine diphosphate.) After dialysis they were diluted five-fold with methanol. The final water content was less than 1 per cent. No dependence of molecular properties on water content was observed for values of the latter less than 5 per cent.

Table 1

Solvent	Water (0·001 *M* sodium acetate)	Methanol (0·001 *M* sodium acetate)
Absorbancy ($\lambda = 260$ mμ (20° C.))	9,500	13,600
Absorbancy* ($\lambda = 260$ mμ (50° C.))	12,400	13,600
Sedimentation coefficient ($S^{20}_{0,w} \times 10^{13}$)	6·9	50
Intrinsic viscosity	16·8	0·26
Optical rotation ($[\alpha]_d$)	+ 100°	− 25

* Corrected for thermal expansion of solvent.

The results (Table 1) can be summarized briefly: The high degree of dextrorotation ($[\alpha]_d$ = 100–150°) normally characteristic of the alkaline form of poly A in water[3,4] is, in methanol containing 0·001 *M* sodium acetate, replaced by a small negative rotation.

Furthermore, most of the hypochromism displayed by poly A in water disappears in methanol solution, as Table 1 shows. The absorbancy at 260 mμ increases by more than 40 per cent in the latter medium and becomes independent of temperature. Inasmuch as the absorbancy of the monomer, adenosine monophosphate, was found to be the same in water and in methanol there is a definite implication that the result with poly A reflects some modification in the secondary structure or conformation of the polymer.

The macromolecular properties of poly A underwent an equally dramatic change. A profound increase in the sedimentation coefficient and a decrease in intrinsic viscosity occur in methanol solution, as has already been observed in the case of DNA (refs. 1 and 2).

All these effects were reversible on removal of methanol by dialysis versus water.

The effect of methanol upon the over-all *macromolecular* properties of poly A is entirely in harmony with the reported results upon DNA. In both cases a dominant factor in the molecular collapse is undoubtedly the largely ion-paired character of the phosphate groups in alcoholic solution[2]. The electrostatic stress, which is important for aqueous solutions of polyelectrolytes at the low ionic strength (0·001) of these investigations, is thus largely relieved.

Thus the apparent helical content of poly A largely disappears in methanol, as judged by both the hypochromism and optical rotation criteria.

Toxicity of 2-(2-Halogen-4-Chlorophenyl)-2-(4-Chlorophenyl)-1,1,1-Trichloroethanes to Normal and to DDT-Resistant House-Flies

As part of a programme designed to test a free-radical hypothesis of insecticidal action for DDT[1], a series of new DDT compounds substituted by halogen in the ortho-position was synthesized and the toxicity to normal and to DDT-resistant house-flies (*Musca domestica* L.) was determined (Table 1). The results are of unusual significance in regard to : (1) the mechanism of DDT resistance, and (2) the relative toxicity of the positional isomers of DDT.

In the susceptible *S*-strain of the fly, a direct correlation exists between the size of the halogen in the ortho position and the LD_{50} value. A reverse correlation is evident with *in vitro* enzymatic dehydrochlorination. If this detoxication mechanism is indeed the basis for DDT-resistance in the resistant *R*-strain, the toxicity of these compounds to the tolerant strain should be the resultant of these two inverse relationships. Results support this supposition with the maximum insecticidal effectiveness occurring in the 2-(2,4-dichlorophenyl)-2-(4-chlorophenyl)-1,1,1-trichloroethane (III).

Table 1. TOXICITY SPECTRA OF DDT ANALOGUES TO SUSCEPTIBLE AND RESISTANT HOUSEFLIES AND CORRELATION WITH DEHYDROCHLORINASE ACTIVITY

			LD_{50} (μgm./♀ fly)		Relative enzymatic dehydrochlorination (*in vitro*)
Compound	*X*	*Y*	*S*-strain (CSMA)	*R*-strain (DDT-45)	*R*-strain Brei
I	H	Cl	0·1	> 40	+ + + +
II	F	Cl	0·2	14·0	+ +
III	Cl	Cl	0·4	0·8	+
IV	Br	Cl	1·1	2·0	–
V	H	H	3·3	> 40	+ + +
VI	Cl	H	6·2	~ 30	–

LD_{50} values are averages of duplicated tests made on at least two successive generations of 5-day-old flies. Each point on dosage–mortality curve was determined by topical application (in 1 μl. acetone) to 80–100 female flies. Treated flies were held at 75–80° F. and percentage mortality recorded at 24 hr. Enzyme activity was measured on a concentrated homogenate of *R*-strain, assayed by the glass bead procedure (ref. 3).

The toxicity spectrum with the *S*-strain indicates that mono-ortho substitution by a chlorine atom reduces toxicity of the parent compound by a small factor. (Compare I with III and V with VI.) When one observes the much greater difference in toxicity between I and V and between III and VI, it becomes evident that the weak activity of VI is primarily the result of the loss of the para-substituent. Hindrance of 'free rotability' of the benzene rings[2] by a single ortho-chloro-substituent can only be of lesser importance in reducing the insecticidal properties of the molecule. The possibility that samples of VI may contain a small amount of I and thus account for the toxicity of the former compound to *S*-strains may be raised. Barring synergism, the fact that VI is still somewhat toxic to the *R*-strain would appear to preclude this possibility.

Further work is in progress to evaluate these and related compounds against different fly strains, naturally tolerant insects, and species with acquired resistance. Selection experiments are also being conducted to determine if the house fly has the capacity to develop resistance to these new compounds. Data on the methods of synthesis and characterization of these new compounds will be published elsewhere.

MINERALOGY and GEOLOGY

Infra-red Investigation of the Migration of Lithium Ions into Empty Octahedral Sites in Muscovite and Montmorillonite

In work on the reaction of molten salts with layer-lattice silicates, it was found that molten lithium nitrate removed a large portion of the potassium from muscovite ($< 5\mu$) and lithium was fixed in a not readily exchangeable manner[1]. It was suggested that lithium ions migrated into the vacant octahedral positions of the dioctahedral micas in a manner similar to that postulated previously by Hofmann and Klemen[2] and Greene-Kelly[3] for lithium-saturated montmorillonite on heat treatment. X-ray diffraction measurements of the 060 spacing of muscovite treated with lithium showed no significant increase, whereas an increase might be expected in conversion of a dioctahedral composition to a trioctahedral composition. Attempts to apply the infra-red technique of Serratosa and Bradley[4] for determination of the orientation of OH-bond axes to indicate formation of a trioctahedral composition were also unsuccessful.

Stubican and Roy[5] observed that an increase in the amount of magnesium in octahedral sites in a muscovite-phengite series caused the absorption band with frequency 935 cm.$^{-1}$ to become more poorly defined. They allocated this band to H–O ... X^{3+} by comparison of spectra for minerals with their deuterated synthetic analogues, and showed that it moves from 935 to 910 to 827 cm.$^{-1}$ as the ions change from aluminium to gallium to iron. Serratosa[6] has assigned the 915 cm.$^{-1}$ band in montmorillonite to H–O... Al^{3+} on the basis that this band decreases in intensity at a rate concomitant with those of the stretching frequency (3,600 cm.$^{-1}$) on heating to successively increased temperatures.

The dioctahedral compositions of the muscovite and montmorillonite structures provide each structural OH with two octahedral ion neighbours, predominantly aluminium in these two minerals. The effect of heavier octahedral neighbours or a greater number of neighbours on the OH bending frequency is considerable[5,6].

If lithium ions enter the empty octahedral sites in muscovite and montmorillonite, one would expect that the three octahedral neighbours (2 Al, 1 Li) of the OH would anchor it more firmly and lower its bending frequency. Fig. 1 shows superposed absorption records of the 5–2μ fraction of (*A*) untreated muscovite (Delamica) and (*B*) the same material after treatment with molten lithium nitrate for 480 hr. The absorption feature appearing at 915 cm.$^{-1}$ in the untreated muscovite is absent after the treatment with lithium nitrate. In addition, the features at 828 cm.$^{-1}$ and 798 cm.$^{-1}$ are eliminated. Treatment of montmorillonite (Wyoming bentonite) with molten potassium nitrate at 350° C. did not affect the 915 cm.$^{-1}$ OH bending frequency, whereas treatment with molten lithium nitrate at 300° C. eliminated the band. These results give experimental verification of migration of lithium ions into empty octahedral sites in muscovite and montmorillonite as postulated previously.

A more detailed account of this work will be published elsewhere. We acknowledge helpful discussions with Dr. W. F. Bradley. The work was supported in part by a grant from the National Science Foundation (*NSF G*6063). The assistance of Dr. John Amy and Marcia Dilling, Chemistry Department, in obtaining the infra-red spectra is gratefully acknowledged.

Mammoths in the Cotswolds

Recent examples of fleeting opportunities provided to archæologists, geologists and others by modern methods of excavation are common knowledge; all too often an opportunity passes before advantage can be taken of it. The following notes illustrate the fruits of sustained observation on one hand, and of good fortune on the other, which we have witnessed in the past year or so.

First, pits worked over a period at Great Chessells, near Bourton-on-the-Water, Glos., in a headwater tributary of the Windrush, were watched by Mrs. Helen E. O'Neil, because she was excavating a Romano-British site progressively destroyed by exploitation. She obtained from the gravels an important collection of mammoth teeth and two molars of woolly rhinoceros[1]. They are comparable with material collected over many years from the lower gravels of the Summertown–Radley terrace of the Upper Thames and its tributaries around Oxford. The association united the deposits of the headwaters of one such tributary, namely, the Windrush, with those of its confluence with the Thames.

Further, material of the same form as these molars of mammoth was recovered recently by one of us

(L. R.) from gravels of the Severn near Worcester[2], and it is known in those of the Avon[3,4].

Within recent months, two notable and unique additions have been made, namely, a comparable molar from the Cheltenham Sands at Charlton Kings[5], and a specimen from the Paxford gravel at Ditchford, between Stretton-on-Fosse and Moreton-in-Marsh, Glos., which again we owe to Mrs. O'Neil.

The molar from Ditchford raises old issues because the succession there was studied years ago by Dr. Mabel Tomlinson[4], who concluded that the gravel lay between two glacial deposits, an older or Campden Tunnel Drift, and a younger or Moreton Drift. The pit was worked extensively for a short time, and in the autumn of 1960 it was filled in ; but the sections confirmed Dr. Tomlinson's conclusions because we saw all three deposits in continuous working-faces[5]. Although irregular surfaces occurred below and above the Paxford gravel, in some places it passed up from the underlying drift with no more than changes of constituents. At the top the distinctive Moreton Drift, with abundant flints, lay on the gravel, which was in some places strongly disturbed, and in others undisturbed. Thus, in spite of striking differences in the constituents of the three deposits, it would be hard to say that they represent events widely separated in time.

The importance of the molar from the gravel at Ditchford thus lies in the fact that it is associated stratigraphically with glacial deposits, which may be traced into the Avon valley and into the head of the Evenlode. Farther down the latter valley, in the Oxford district, is the region of abundant occurrences of teeth and bones of mammoth with an associated fauna, in the lower part of the Summertown–Radley gravels. The upper part, unconformable on the lower, contains remains of hippopotamus and other mammals, and freshwater molluscs[6].

The tributary of the Windrush mentioned above is separated from the upper reaches of the Evenlode by a ridge of Jurassic rocks near Stow-on-the-Wold.

If mammoth teeth found in the various deposits recorded in this communication may be accepted as a common and diagnostic palæontological factor, a sense of contemporaneity is introduced between gravels of the Upper Thames and its tributaries, and of the Severn and Avon, glacial deposits, and the Cheltenham Sand (which in part may be of æolian origin). In fact the molars are known widely, from the Cotswolds to the Lower Severn (for example, Barnwood) and to the Midlands, and they are distinctive: the 'Siberian' form, known also in younger deposits, sometimes occurs. Consequently, the significance of the several deposits and the tooth in the Ditchford pit, close to the divide between the Thames and Severn systems, can be readily determined, and the result is valuable in connexion with the correlation of the superficial deposits in the basins of the two rivers.

BIOCHEMISTRY

Comparison of the β-Lactoglobulins of Buffalo's Milk and Cow's Milk

Aschaffenberg and Drewry[1,2] demonstrated by paper electrophoresis at pH 8·6 that β-lactoglobulins of cow's milk (sometimes described in the literature as bovine β-lactoglobulin) occurred in two different forms, β-lactoglobulin A and β-lactoglobulin B. The milk of individual animals contained either both or only one of these components, and the formation of these proteins by the mammary gland was genetically controlled. These observations led to the present work on the whey proteins of buffalo's milk, which is widely consumed in India and other eastern countries, to see whether such a possibility existed among this species of animal.

The typing procedure of Aschaffenberg and Drewry[3] was applied to individual samples of milk collected from 70 buffaloes and also to two samples of pooled milk. The animals belonged to mixed breeds with features of one or other of the common Indian buffaloes[4] relatively dominant. Paper electrophoresis experiments were carried out in barbitone buffer of pH 8·6 ($I = 0{\cdot}05$), applying a voltage of 240 V., by both hanging- and horizontal-strip techniques, using Whatman No. 4 filter paper. A sample of whey proteins of cow's milk containing almost equal proportions of β-lactoglobulins A and B was run as a standard for comparison with each experiment. It was found (Fig. 1) that buffalo's milk contained only one type of β-lactoglobulin which migrates to the position corresponding to the β-lactoglobulin B of cow's milk. In view of the fact that the same results were obtained from as many as 70 individual samples, it appears that the genetic control as reflected in the case of cow's milk, does not exist in the buffalo.

The electropherograms also reveal a distinctly different movement of the α-lactalbumin band of the buffalo's milk from that of cow's milk, the former moving ahead of the latter. This offers a possibility of developing a method, which is being explored, of detecting adulteration of one by the other.

The buffalo β-lactoglobulin crystallized in diamond shaped form and the lactalbumin in needles when the

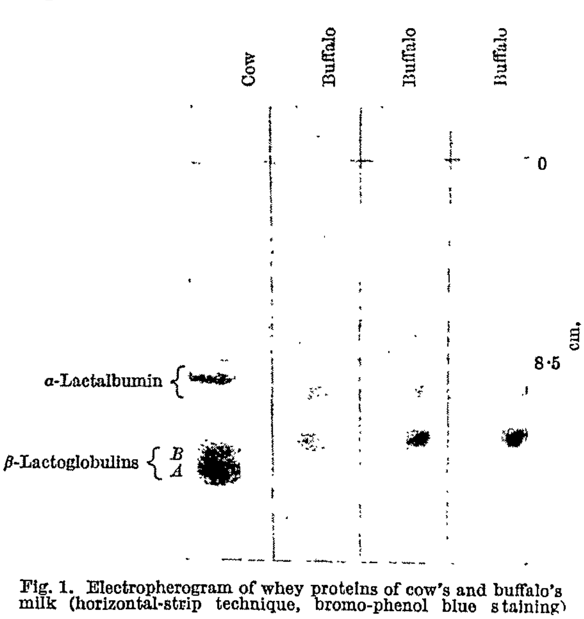

Fig. 1. Electropherogram of whey proteins of cow's and buffalo's milk (horizontal-strip technique, bromo-phenol blue staining)

method of Aschaffenberg and Drewry[3] with minor modifications was employed. Preliminary electrophoretic experiments in a Tiselius apparatus, of crystalline buffalo β-lactoglobulin, indicated its isoelectric point to be approximately 5·25 and the electrophoretic patterns obtained near the isoelectric point with acetate buffers of 0·1 ionic strength were found to be asymmetrical or partially resolved on the descending side and hypersharp on the ascending side. Sedimentation experiments with a Spinco model *E* analytical ultracentrifuge with protein concentrations up to 6·8 per cent and at 20° C. and low temperatures (about 8° C.) gave symmetrical patterns. These results show that there is close similarity between physico-chemical properties of buffalo β-lactoglobulin and β-lactoglobulin *B* of cow's milk[5,6].

Further work is in progress and details will be published elsewhere.

We are indebted to Messrs. Alpine Dairy and Farm, Agarpara, W. Bengal, and particularly to Mr. B. K. Choudhury for supplying the milk and helping in identification of individual animals.

Intracellular Distribution of Ubiquinone in Rat Liver under Certain Stress Conditions

OBSERVATIONS on the effects of pantothenic acid deficiency on mitochondrial composition in relation to oxidative metabolism in rat liver were reported earlier[1]. In the present communication, observations on intracellular distribution of ubiquinone in the pantothenic acid-deficient rat liver are presented. The effects of vanadium administration and of vitamin A-deficiency have also been studied, since vanadium is known to cause decreased hepatic coenzyme *A* (ref. 2) and vitamin A-deficiency results in increased ubiquinone-level[3].

Dietary deficiencies of pantothenic acid and vitamin A were produced by feeding weanling rats (40–50 gm.), Wistar strain, a 10 per cent purified casein ration deficient in the respective vitamin and replete in all other respects, for a period of 8 weeks. To one group of rats, fed the casein ration with all the vitamins, ammonium vanadate was administered intraperitoneally (0·6 mgm./rat/week), throughout the experimental period. The animals were killed, livers quickly removed and chilled in cracked ice. Livers were homogenized in isotonic (0·25 *M*) sucrose, nuclear and mitochondrial fractions separated in a *PR*-2 International refrigerated centrifuge[4] and microsomes in a Spinco preparative centrifuge[5]. Determinations of coenzyme *A*, ubiquinone and mitochondrial succinoxidase activity were as described before[1]. The supernatant fraction was freeze-dried before saponification in the assay procedure for ubiquinone.

The results (Table 1) show normal rat liver ubiquinone to have an average distribution of 29·1 per cent in the nuclei, 37·8 per cent in the mitochondria, 14·9 per cent in the microsomes and 5·5 per cent in the supernatant fraction. Of the total coenzyme *Q*, 84–93 per cent was recovered in the various cytoplasmic fractions.

Vanadium administration, as also pantothenic acid-deficiency, result in marked and very similar decreases in total coenzyme *A*, mitochondrial ubiquinone and succinoxidase activity. This close parallelism suggests that the reduced hepatic coenzyme *A*-level is the primary cause of the decrease in ubiquinone; the involvement of coenzyme *A* in the biosynthesis of the isoprenoid side-chain of the ubiquinone molecule is known (cf. ref. 1). Vitamin A-deficiency results in elevated levels of ubiquinone in all the cell fractions, being particularly marked in the microsomal and supernatant fractions and is unattended by any change in succinoxidase activity.

10 per cent casein − vitamin A	187 ± 11·6	46 ± 3·9	61 ± 6·2	34 ± 2·4	17 ± 4·1	—	1,361 ± 98

Results are averages of four independent determinations ± *S.E.*, and are expressed per gm. fresh liver weight.

Extraction of Nucleic Acid-free Lipopolysaccharides from Gram-negative Bacteria

THE extraction of Gram-negative bacteria by the hot phenol method of Westphal[1] yields a lipopolysaccharide along with considerable amounts of nucleic acid. The nucleic acid can be separated from the high molecular weight lipopolysaccharide by high-speed centrifugation, but to reduce the nucleic acid to a level of less than 2 per cent may require four or five sedimentations.

It is known that when the trichloracetic acid method of Boivin is used to extract the somatic antigen, a considerable amount of the antigen may remain in the residue[2]. Working with a *Pseudomonas* species, we have found that the residue left after the dried cells have been treated with trichloracetic acid, can be extracted with phenol to yield a lipopolysaccharide virtually free from nucleic acid.

10 gm. of the acetone-dried cells were mixed for 3 hr. in 100 ml. of 0·25 N trichloracetic acid at a temperature of 2–4° and then centrifuged. The deposit was washed with 100 ml. of distilled water and again centrifuged. This deposit was then extracted with 45 per cent phenol at a temperature of 65–67° and, after cooling, the aqueous phase was separated, dialysed, centrifuged at 4,000 r.p.m. for 10 min. to remove debris, and the supernatant was then freeze dried. The yield of extracted material from different batches was between 300 and 400 mgm. This compares favourably with the yield of lipopolysaccharide obtained after removal of the nucleic acid by high-speed centrifugation.

The lipopolysaccharide obtained by this method contained no detectable amounts of nucleic acid and was highly pyrogenic in rabbits in doses of 0·01 μgm./kgm. body-weight. Preliminary analysis showed the presence of galactose and glucose and 45–50 per cent of a lipid soluble in chloroform.

Similar results have been obtained with *E. coli* 0111 (supplied by Dr. O. Lüderitz) and with *P. vulgaris*. In both cases the modified extraction procedure yielded highly pyrogenic, nucleic acid-free lipopolysaccharides in amounts equivalent to 2–3 per cent of the dry weight of the bacteria.

The results with these three organisms suggest that pre-treatment with trichloracetic acid before phenol extraction may be a general method of obtaining nucleic acid-free lipopolysaccharides without the lengthy procedure of high-speed centrifugation. This suggestion is supported by unpublished observations made by D. A. L. Davies (personal communication) working with different bacteria.

Enzymatic Reduction of Diphosphopyridine Nucleotide with Urea

In investigating the properties of an enzymatic cycle between ammonia and nitrate[1], we have now observed the enzymatic reduction of diphosphopyridine nucleotide with urea.

The enzyme solution was prepared daily from acetone precipitates of fresh fowl liver according to the procedure already described[1]. To measure the activity, 1 ml. of 0·025 per cent solution of diphosphopyridine nucleotide was mixed with 1 ml. of enzyme solution, 1 ml. of 0·001 M urea solution and 0·5 ml. of 0·2 M *tris* buffer of *p*H 7·5. Then, the increase (+) in absorption ($-\log T$) at 340 mμ was determined by a spectrophotometer at 30° C. after 30 min. As shown in Fig 1, $-\log T$ increased in the presence of urea, and a slight increase was observed in the control which contains no urea. This value must therefore be subtracted from those in tests. In the reaction mixture without enzyme, there was no change in $-\log T$. The increase of $-\log T$ was rapidly reduced when alcohol dehydrogenase and acetaldehyde were added.

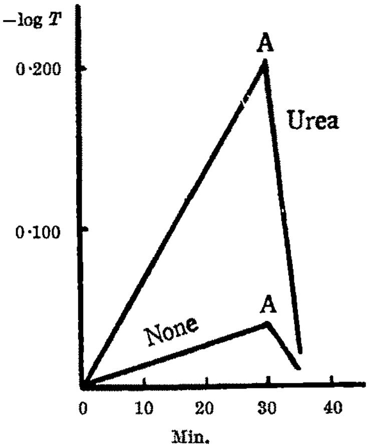

Fig. 1. Reduction of diphosphopyridine nucleotide with urea. At point *A*, alcohol dehydrogenase and acetaldehyde were added

The reduction does not proceed in a mixture containing phosphate buffer. The enzyme exhibits its highest activity at 35° C. and *p*H 7·5 ; it is activated by heating at 35–40° C. for 5 min. but destroyed at 60° C. Diphosphopyridine nucleotide is reduced with biuret or monomethylurea too, although at a slower rate than with urea.

However, it is thought that the enzymatic reduction of diphosphopyridine nucleotide may be attributed to ammonia produced from urea by the action of urease, since the nucleotide is reduced by the same enzyme solution in the presence of ammonium salts. Therefore, the formation of reduced diphosphopyridine was examined comparatively with urea and ammonium sulphate, although distinct formation of ammonia from urea by the enzyme solution employed was not established.

Table 1 shows that triphosphopyridine nucleotide can also be reduced by urea, whereas only the diphosphopyridine nucleotide is reduced with ammonia.

Table 1. REDUCTION OF DI- AND TRI-PHOSPHOPYRIDINE NUCLEOTIDE

Nucleotide	DPN			TPN		
Substrate	Urea	Ammonia	None	Urea	Ammonia	None
$-\log T$	+0·113	+0·140	+0·025	+0·068	+0·009	+0·009

Reduction of diphosphopyridine nucleotide with ammonia accompanies the formation of its oxidation products, hydroxylamine, nitrite and nitrate. On the other hand, as illustrated from Table 2, these substances could not be demonstrated in the case of urea.

Table 2. FORMATION OF HYDROXYLAMINE, NITRITE AND NITRATE IN THE REACTION MIXTURE

Product		Hydroxylamine	Nitrite	Nitrate
Substrate	Urea	0	0	0
	Ammonia	4×10^{-6} M	4×10^{-6} M	1×10^{-5} M

Further work showed that there are some other differences between the reduction of diphosphopyridine nucleotide with urea and that with ammonia, especially in connexion with the re-oxidation of the reduced nucleotide formed by nitrate reductase in the reaction mixture, substrate inhibition, optimum temperature and purification of enzyme.

On the basis of this work, the reduction of diphosphopyridine nucleotide with urea may be an enzymatic electron transfer from urea to the nucleotide, and not from ammonia in association with urease and ammonium dehydrogenase. In other words, the reaction appears to be an enzymatic dehydrogenation of urea which serves as an electron donor. This reaction has not previously been observed so far as we know. However, it should not be called urea dehydrogenase, until the dehydrogenation products of urea are established and the reaction mechanism is explained. Work is in progress to do this.

A D-Lactic Dehydrogenase from *Leuconostoc mesenteroides*

The properties of the L-lactic dehydrogenases (L-LDH) from muscle[1-3] and yeast[4-6] have been studied extensively. Recently, the presence of lactic dehydrogenases was reported in animal tissues[7], yeast[8-10] and bacteria[11-13], specific for the D-isomer of lactic acid. The present communication describes the isolation, partial purification and some properties of a D-lactic dehydrogenase (D-LDH) from *Leuconostoc mesenteroides*.

L. mesenteroides strain No. 8042 was grown without shaking on a proteose peptone medium, containing 1 per cent glucose. The cells were collected after 24 hr. growth and disintegrated sonically. The sonicate was centrifuged at 105,000*g* for 2 hr. The supernatant extract contains D- and L-LDH activity in a ratio of 20 : 1. This ratio could be increased to more than 200 : 1 by fractionation with ammonium sulphate, using the fraction precipitating between 0·15 and 0·40 saturation. At the same time the specific activity towards D-lactate was increased threefold. In the experiments described here, this partially purified preparation was used.

Dehydrogenase activity was assayed by the reduction of 2,6-dichlorophenol-indophenol (DCPIP) (1×10^{-4} *M*), measured by the decrease of optical density at 620 mμ. The assay was carried out in phosphate buffer (0·25 *M*) at *p*H 6·5, which was found to be the optimum under ærobic conditions. The enzyme preparation contained approx. 5 mgm. protein/ml. The K_m with regard to D-lactate was found to be $1{\cdot}5 \times 10^{-3}$ *M*. In the following experiments a 2×10^{-2} *M* substrate concentration was used.

In contrast to yeast LDH[1,2], neither ferricyanide nor cytochrome c nor molecular oxygen could replace DCPIP as hydrogen acceptor. Added di- or triphosphopyridine nucleotide (DPN, TPN) at a concentration of 2×10^{-3} *M* had no effect on the rate of reduction of DCPIP. Moreover, DPN did not serve as a hydrogen acceptor for D-lactate, nor could DPNH pass on its hydrogen atoms to pyruvate. Flavin adenine dinucleotide or flavin mononucleotide had no effect on the system.

Table 1. Substrates and Inhibitors of D-LDH from *L. mesenteroides*

Substrates	Relative velocity	Inhibitors	I_{50} (*M*)
D-Lactate	1·00	pyruvate	0·05
L-Lactate	0·005	fluoropyruvate	0·001‡
DL-Fluorolactate*	0·15	oxalate	0·0005
DL-Chlorolactate	0·03	copper†	0·0001
DL-α-Hydroxy-butyrate	0·01	mercury†	0·00005
DL-glycerate	0·01		

* In presence of 0·01 *M* hydrogen cyanide; without hydrogen cyanide the enzyme was rapidly inactivated.
† After 15 min. pre-incubation with the enzyme.
‡ Calculated from activity of DL-fluorolactate without hydrogen cyanide.

Table 1 shows the substrate specificity and the effect of inhibitors. It can be seen that the substitution at the β-carbon sharply decreases the activity, in contrast to the yeast enzyme[6] and more resembling the muscle enzyme[1]. Other α- and β-hydroxy acids were not attacked, nor were glycolic acid and the ethyl ester and amide of *d,l*-lactic acid.

The enzyme differs from the flavoprotein yeast LDH in the lack of inhibition by atebrin[4] and *d,l*-mandelic acid[6]. In contrast to muscle L.LDH, *p*-chloromercuribenzoate (2×10^{-4} *M*) and iodoacetate (1×10^{-2} *M*) were without effect. Strong inhibition was caused by oxalate. Fluorolactate inhibited strongly in the absence of hydrocyanic acid, while it acted as a substrate in its presence. Moreover, fluoropyruvate did not inhibit the enzyme. This finding indicates that the product formed as a result of the dehydrogenation of fluorolactate is not identical with the synthetic product. Differences in inhibitory activity between various forms of fluoropyruvate have been described already by Busch and Nair[14]. Zinc, molybdenum, nickel, manganese, cobalt and iron (all at 1×10^{-3} *M*) did not affect enzyme activity, but copper and mercury were strong inhibitors, their effect being reversed not only by cysteine, but also by histidine, both of them at a tenfold excess over the metal ion concentration.

The *Leuconostoc mesenteroides* D-LDH resembles some of the bacterial D-LDH's described[9-11]. However, it is most closely related to that of Molinari and Lara[12] in *Propionibacterium pentosaceum* but differs from the latter in not being inhibited by atebrin and SH-agents. In the enzyme described in this communication the nature of the active site is not clear.

Stimulation of Active Transport of Sodium from Sodium-rich Frog Muscle by Insulin and Lactate

ACTIVE excretion of sodium from muscle was first shown for rat muscle *in vivo* by Conway and Hingerty[1], and for isolated frog muscle by Desmedt[2] and by Conway *et al.*[3]. The latter workers found that when the sodium-level of muscle fibres was increased to about 60 mM/l. fibre water, by overnight immersion in cold potassium-free Ringer–Conway fluid containing 120 mM/l. sodium, it was necessary to reduce the external sodium in the presence of 10 mM/l. potassium chloride before active extrusion of sodium would occur.

The concept of a critical energy barrier to extrusion of sodium was introduced by Conway[4,5] to explain the necessity of reducing the external sodium, or of increasing the external potassium concentration above its normal level in plasma for excretion of sodium to occur. The energy barrier takes account of the electrical and osmotic gradients against which the sodium is extruded and is expressed by the relation:

$$dG/dn = RT.\ln [\mathrm{Na}]_o/[\mathrm{Na}]_i + E_m F \qquad (1)$$

where dG/dn is the free energy change per equivalent of sodium extruded, E_m the mean membrane potential of the muscle fibres (outside minus inside) in the recovery fluid, measured by the micro-electrode technique[6], and $[\mathrm{Na}]_o$ and $[\mathrm{Na}]_i$ the sodium concentrations in the recovery fluid and fibres respectively. In previous experiments[5], it was found that under the conditions used, sodium could not be extruded against a barrier greater than 2,000 cal., but it could be extruded if the barrier was reduced by lowering Na_o or by increasing K_o, and thereby reducing E_m.

In the presence of 30 units of insulin and 1 mM lactate per litre recovery fluid, I found that with muscles loaded with sodium as described above, the extrusion of sodium would occur, and at the normal plasma potassium-level of 2·5 mM/l. against an external sodium concentration of 120 mM/l. (see Table 1). At the same time about 30 mM potassium was gained by the muscles. It was found that the energy barrier against which sodium was extruded was 2,500 cal. at time of re-immersion in recovery fluid, rising to about 3,000 cal., after 3 hr., as extrusion reached completion. The mean membrane potential was 96 ± 0·9 mV. on re-immersion falling to 90 ± 1·9 mV. towards the end. The energy barrier here was closer to that computed for the intact animal[5], namely, 4,000 cal.

Examining the chloride movement under the conditions of previous experiments[5], I found that during immersion in potassium-free Ringer fluid the muscles gained an average of 20 mM chloride per litre fibre water, and that this chloride remained in the fibres even when the sodium had been extruded in exchange for potassium. However, addition of insulin and lactate to the recovery fluid produced a marked decrease in the fibre chloride.

The effect of some inhibitors on the extrusion of sodium under these conditions is summarized in Table 1.

It would appear from these experiments that the fall of the critical energy-level of extrusion of sodium from isolated muscle is related to a fall in the maximum electro-chemical potential at which the sodium pump can excrete sodium ions. In the light of these observations, and those of Manery *et al.*[7,8] it seems possible that insulin and lactate may play a part in the extrusion of sodium from frog muscle *in vivo*. They may also be the active constituents of plasma, which prevent the loss of potassium from isolated frog muscle[9], and maintain the membrane potential of the muscle at a higher value than found using Ringer fluid as immersion fluid[10]. In this connexion it may be of interest to note that Zierler[11] has reported that insulin increases the membrane potential of isolated muscle of rat.

Table 1. FROG SARTORII SOAKED OVERNIGHT AT 0° C. IN POTASSIUM-FREE RINGER FLUID CONTAINING 120 mM SODIUM, THEN RE-IMMERSED FOR 3 HR. AT ROOM TEMPERATURE (18° C.) IN FLUID CONTAINING 120 mM SODIUM, 2·5 mM POTASSIUM, 1 mM LACTATE AND 30 UNITS OF INSULIN PER LITRE

(Mean value after first immersion—60·6 ± 4·2 mM/l. fibre water)

Inhibitor used	Sodium concentration in muscle (mM/l. fibre water) Control	Inhibited
Ouabain (10^{-6} M/l.)	25·4 ± 1·4	46·1 ± 1·8 (11)
Iodoacetate (2 mM/l.)	23·2 ± 2·5	65·8 ± 3·6 (14)

Companion muscles were used. No. of experiments shown in brackets.

My thanks are due to Prof. E. C. Conway for advice and discussion, and to the Medical Research Council of Ireland for grants-in-aid.

PHYSIOLOGY

Urocanicacidurea associated with Hepatic Coma

WHILE studying the urinary chromatographic pattern of a patient in hepatic coma the presence of an abnormal spot R_F 0·14 and 0·54 in propanol/ammonia, 7 : 3, and butanol/acetic acid/water, 4 : 1 : 5, respectively, was noted after spraying paper chromatograms with diazotized *p*-sulphanilic acid. This colour reaction suggested that it might be an imidazole derivative, yet chromatography excluded the possibility of it being histamine, histidine or 1-methylimidazole-4-acetic acid (Table 1). As the presence of this unknown compound could not be related to the diet, or therapy, of the patient and appeared to be associated with the disease, an attempt was made to isolate it.

A 24-hr. urine sample was concentrated and acetone-precipitated according to the method of McIsaac and Page[1]. The final concentrate was streaked on Whatman No. 1 paper and chromatographed in butanol/acetic acid/water, 4 : 1 : 5. The corresponding transverse strips of paper with R_F 0·5–0·6 were eluted with ethanol. The eluates were pooled and evaporated to dryness to yield 15 mgm. of crystalline material. Recrystallization from water yielded 10·6 mgm. of chromatographically pure white crystals of urocanic acid (imidazole acrylic acid), m.p. 229° C., mixed m.p. 228–29° C., $\lambda_{\text{max.}}$ 277 mμ (pH 7·4)[2] (found : C, 40·9 ; H, 5·9 ; N, 16·0 per cent ;

Table 1

	Colour of spots on paper with			R_F values in solvent	
	Nin-hydrin	Diazo-*p*-sulphanilic acid	Methyl red	*A*	*B*
Histamine	None	Red	—	0·46	0·20
Histidine	Blue	Red	—	0·15	0·10
Methylimidazole acetic acid	None	None	Pink	0·29	0·21
Imidazole acrylic acid (Urocanic acid)	None	Orange	Pink	0·14	0·54
Isolated compound	None	Orange	Pink	0·14	0·54

R_F values and colour reactions of compounds used. Solvent systems used were: *A*, propan-1-ol/ammonia, 7 : 3 and *B*, *n*-butanol/acetic acid/water, 4 : 1 : 5.

$C_6H_6O_2N_2 . 2H_2O$ requires C, 41·4 ; H, 5·8 ; N, 16·0 per cent).

Urocanic acid, an intermediary breakdown product in the metabolism of histidine to glutamic acid, is not normally excreted in the urine, and has only been observed after animals have been given large doses of histidine[3]. The present finding of an abnormally large amount of urocanic acid in the urine of a patient with hepatic necrosis would indicate that the pathological lesion was associated with a biochemical lesion of the enzyme system urocanase. The failure of the metabolic degradation of urocanic acid in the liver parenchyma might well have caused a deficiency of the ammonia-detoxifying glutamic acid which in part may have been responsible for the high blood ammonia-levels observed in this case.

A detailed case-history of this patient will be reported elsewhere.

We are indebted to Mrs. Pamela Taylor who did the isolation work, and we wish to thank Dr. R. W. Schayer, of the Merck Institute for Therapeutic Research, for supplying us with 1-methylimidazole-4-acetic acid.

Effect of Chronic High and Low Salt Intakes on Adrenocortical Function

We have presented evidence which suggests that a high salt intake may be related to the development of human essential hypertension[1], and that a prolonged low salt intake is compatible with apparently normal adrenocortical function[2].

Reference[1a,2] was made to observations by others which had been interpreted to indicate that a low salt diet could be harmful by causing hypofunction of the adrenal cortex with the organism thereby rendered less responsive to stress. Such inferences were in sharp contrast to our own experience with more than 125 persons whose daily salt intake was known to have been restricted to levels ranging from 30 to 375 mgm. for periods up to 5 years[3].

In one of the reports[2] adrenocortical function appeared to be within normal limits in 3 individuals who had been maintained on daily intakes of 250–375 mgm. salt for periods of from 1 to almost 5 years. Nevertheless, since no evaluation had been made prior to salt restriction a subtle decline in adrenocortical responsiveness might have remained undetected.

Recently it became possible to re-evaluate adrenocortical activity (as this is indicated by the response to the 48-hr. adrenocorticotrophic hormone infusion test of Jenkins *et al.*[4]) in two of these same individuals when salt intake was resumed after 23 and 35 months of drastic salt restriction, respectively. The two ambulatory patients were White bachelors aged forty-nine and fifty-one years on admission. They had uncomplicated essential hypertension, and were capable of long walks on the Laboratory site daily. All menus were calculated by a dietitian, and the food was prepared and weighed in a diet kitchen. Both men were required to eat all and only the food provided. When salt was added to the regimen it was given as enteric-coated tablets under observation. Continuous 24-hr. urine collections for sodium content indicated compliance with the prescribed diet. Over a period of four months gradual increments of salt were made until during the 3 weeks preceding, and at the time of, the present work each patient was eating 40 gm. of sodium chloride daily. This is a very high salt intake by American standards[5], but these men had no symptoms from it. However, their blood pressures, which had dropped markedly on salt restriction, rose significantly on addition of salt.

Table 1 summarizes the present findings, and compares them with the results of this same test performed at various intervals during the period of salt restriction. It will be seen that the fall in total circulating eosinophiles following the infusion of adrenocorticotrophic hormone on each of days 3 and 4 was similar in these subjects whether they were off or on salt. By contrast, the urinary excretion of 17-ketosteroids and 17-hydroxycorticoids appeared to be somewhat decreased on the high salt intake. This was manifested both by smaller quantities of steroid excreted and by a response which was delayed until after the second infusion of adrenocorticotrophic hormone.

Table 1. 48-hr. Adrenocorticotrophic Hormone Test for Adrenocortical Reserve Function

			N.S. ♂ 51 years		R.B. ♂ 49 years			
Months off (−) or on (+) salt			− 12	+ 4	− 13	− 18	− 25	+ 4

25 units of adrenocorticotrophic hormone infused over an 8-hr. period on each of days 3 and 4.

It would be premature to interpret the present studies as indicating that a high salt diet can impair adrenocortical function. The prompt, marked fall in total circulating eosinophiles when these patients were on the high salt intake is highly suggestive of a normally functioning adrenal cortex. Furthermore, evaluation of adrenocortical steroid production by means of urinary steroid excretion must always be suspect. Nevertheless, the results clearly indicate that by this method of estimating adrenocortical responsiveness, a high salt diet is not beneficial and a low salt diet is not harmful.

Hypothalamic Control of Lactogenic Function in the Cat

While it is generally accepted that the hypothalamus controls the systemic release of anterior pituitary prolactin, it still remains to be established where in the hypothalamus the regulatory centres are located and how they mediate their influence.

The present investigation involves the use of a comparatively simple and effective technique which has facilitated systematic study of this problem without the use of drugs, hormones, or pituitary transplantation. It is the result of an incidental observation made by one of us (A. B. R.) that transverse section of the anterior tuber cinereum in the cat resulted in mammary growth and lactation.

A total of ten animals was used, four of which served as controls. In the six experimental cats, the diencephalic floor was aseptically exposed through the transbuccal route under barbiturate anæsthesia and the tuber cinereum sectioned transversely just behind the optic chiasm, so as not to impair the hypophyseal blood supply by injuring the median eminence or portal vessels. In three control animals the similarly exposed tuber cinereum was perforated in the midline by a stab with a large bore (No. 18) hypodermic needle, while in the fourth cat the hypothalamic section was carried out posteriorly, behind the median eminence in the premamillary region. Each operation included the removal of a mammary gland for histological examination and comparison with subsequent mammary biopsy specimens.

Because milk secretion can be induced with prolactin only in cats with fully developed ductal and lobulo-alveolar systems, positive findings can only be obtained in post-partum cats or in cats primed with ovarian hormones. The investigation reported here was confined to post-partum cats the mammary glands of which were allowed to regress over a period of up to two months.

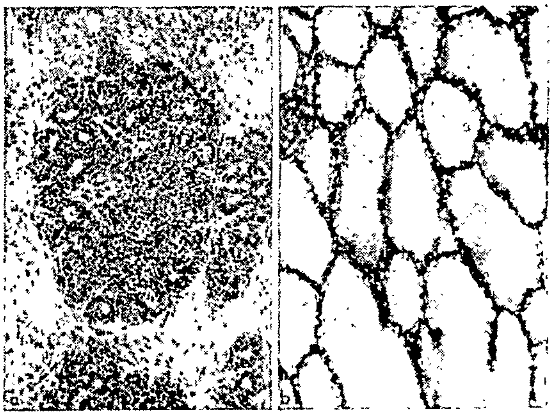

Fig. 1. Photomicrographs of mammary glands showing (*a*) preoperative resting state and (*b*) active secretory state of mammary gland in the same cat 14 days after anterior tuberal section

At the time of the operation, all the mammary glands were flat to inspection and no underlying mammary tissue could be palpated. Within three to twelve days after the tuber cinereum transection all six experimental cats, but none of the controls, showed the onset of mammary growth, which within another few days culminated in mammary hypertrophy and milk secretion indistinguishable from that seen during normal lactation (see Fig. 1).

The diabetes insipidus which often ensued at about the same time bore a variable relationship to these changes: mammary hypertrophy was observed both before and after the onset of the 'normal interphase' which accompanies the release of neurohypophyseal hormones from the degenerating posterior lobe. After a few weeks, a progressive decline in the mammary hypertrophy ensued in all but the one cat from which milk was actively withdrawn under administration of oxytocin. In this case, the involutional process was interrupted by a brief period of renewed growth.

The initiation of the observed mammary changes is known to require stimulation by prolactin. Since in these experiments the discharge of this hormone from the adenohypophysis resulted from the separation of the median eminence and hypophysis from their neural connexions with the anterior hypothalamus, the findings are explained tentatively as due to the removal of anterior hypothalamic inhibition, with or without additional facilitation through the intact posterior and lateral hypothalamic-hypophyseal pathways.

It is of interest to note that in the rabbit a centre inhibiting release of prolactin appears to be located in hypothalamic regions caudal rather than rostral to the hypophysis[1], and in an area of the hypothalamus which appears closely related to the centre controlling œstrus behaviour activated by œstrogen[2]. Since in the cat a corresponding centre controlling œstrus behaviour has been described in the anterior hypothalamus[2], which from this work appears to be the centre inhibiting release of prolactin, it is possible that these lactation-inhibiting regions of the hypothalamus may be topologically associated with the regional hypothalamic control centres sub-serving more complex and purposive patterns of behaviour such as mating and the care of the young. The latter is supported by observations that administration of prolactin to females of some species evokes maternal behaviour[3].

Release of 5-Hydroxytryptamine from Rat Mast Cells *in vitro*

Histamine is released from mast cells following the injection into animals of histamine liberators. Coincident with the release of histamine other substances have been detected in the plasma capable of causing a slow contraction of isolated smooth muscle[1-4]. Paton[4] was able to demonstrate the presence of a 'slow-contracting' substance in addition to histamine in the plasma of cats and dogs following an intravenous injection of the potent histamine release agent, compound 48/80. Preliminary experiments have shown that a similar substance appears in plasma collected from rats 5 min. after an intravenous injection of compound 48/80 (1 mgm./kgm.). The origin of the slow-contracting substance in rat plasma was investigated by means of an *in vitro* system consisting of a solution of compound 48/80, rat plasma, mast cells from the peritoneal cavity of the rat, and an isolated rat uterus preparation.

Mast cells were obtained from the rat by a method previously described[5]. The rat uterus preparation was set up according to the method of Sollero *et al.*[6]. Compound 48/80 was dissolved in physiological saline solution to a strength of 10 μgm./ml. Blood was collected from the jugular vein of rats into a syringe containing heparin (5 units/ml. blood). The blood was transferred to a centrifuge tube and plasma free of platelets obtained by centrifugation. All glassware, including syringes and the organ bath, were siliconed with 'Dri-Film' (General Electric Co.) before use.

A mixture was prepared consisting of 0·1 ml. each of the solution of compound 48/80, fresh heparinized plasma and mast cell suspension (containing approximately 1 million mast cells per ml.). When added to the organ bath the mixture was found to cause a contraction of the rat uterus. A similar contraction was produced in the absence of plasma when 0·2 ml. of a mixture consisting of 0·1 ml. vol. of compound 48/80 solution and mast cell suspension was added. 0·1 ml. of the solution of compound 48/80 alone, or when mixed with an equal volume of plasma and added to the bath, failed to stimulate the rat uterus. Similarly intact mast cells alone or with an equal volume of plasma did not cause a contraction of the isolated uterus. Prior treatment of the isolated uterus for 5 min. with dibenamine (1 μgm./ml.), 2-brom-D-lysergic acid diethylamide, known as BOL 148 (1 μgm./ml.), 1-methyl-D-lysergic acid butanolamide, known as UML 491 (0·2 μgm./ml.), or excess 48/80 (1 mgm./ml.) was found to prevent a contraction of the uterus on the addition to the bath of the mixture containing compound 48/80 and mast cells. These substances are known to inhibit the action of 5-hydroxytryptamine but are not specific. No response of the treated uterus was obtained on the addition to the bath of plasma obtained from rats 5 min. after an intravenous injection of compound 48/80.

This work suggests that a substance capable of causing a contraction of the isolated rat uterus is released from mast cells disrupted by compound 48/80. Histamine is found in mast cells in a concentration of 40 μgm. per million cells, but it does not cause contraction of the rat uterus. The 5-hydroxytryptamine concentration in rat mast cells is approximately 1/20 the concentration of histamine[7]. 5-Hydroxytryptamine was added to the bath in amounts equivalent to the calculated 5-hydroxytryptamine content of 0·1 ml. of the mast cell suspensions, and the resulting uterine contraction was similar to that produced by the mixture containing 0·1 ml. of mast cells and 0·1 ml. of compound 48/80.

The smooth muscle stimulant was released also from mast cells disrupted by a number of procedures shown previously to cause the release of histamine from mast cells[5,8-10] including (*a*) mechanical disruption ; (*b*) distilled water ; (*c*) an extract obtained from rat splenic tissue ; (*d*) dextran, when added to serum obtained from rats following adrenalectomy ; (*e*) addition of human red cells to fresh rat antiserum at 37° C. and *p*H 7. In experiments (*d*) and (*e*) with rat serum it was necessary first to decrease 5-hydroxytryptamine content of the serum by an intraperitoneal injection of reserpine (5 mgm./kgm.) at least 8 hr. before collection of the blood.

It may be concluded that 5-hydroxytryptamine or a similar substance is released together with histamine when rat mast cells are disrupted *in vitro*. It seems likely that this substance is the 'slow-contracting' substance found in rat plasma following the intravenous injection of compound 48/80.

Compound 48/80 used in these experiments was kindly supplied by Burroughs Wellcome (Australia), Ltd., reserpine by Parke Davis and Company, and BOL 148 and UML 491 by Sandoz Australia Pty., Ltd.

Interaction of Acetylcholine, Calcium and Depolarization in the Contraction of Smooth Muscle

Smooth muscle which has been depolarized by external application of potassium still contracts in response to acetylcholine[1]. This response requires calcium (ref. 2, and personal communication from D. H. Jenkinson). Calcium ions alone cause the depolarized smooth muscle to contract. If an isolated rat uterus is immersed at room temperature in calcium-free isotonic potassium sulphate–Ringer (22·0 gm. K_2SO_4, 0·36 gm. $KHCO_3$, 1·0 gm. glucose/litre) it contracts briefly and then relaxes completely. At this stage the application of very low concentrations of calcium (0·1 m*M*) causes the development of a reversible tension. The magnitude of the tension increases with concentration of calcium up to about 1·2 m*M*. Higher concentrations of calcium produce diminishing responses in tension. The maximum tensions developed by calcium are less than the maximum of which the preparation is capable, and they can be increased by acetylcholine. The effect of 10^{-5} acetylcholine added to 2·4 m*M* calcium is shown in Fig. 1.

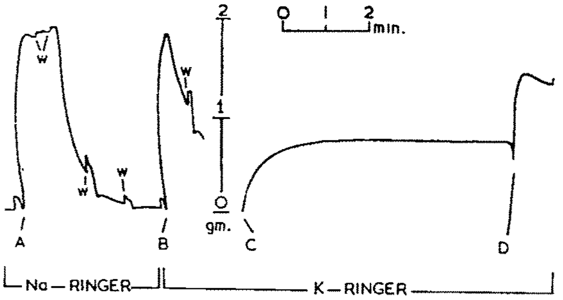

Fig. 1. Effect of acetylcholine superimposed on a maximal calcium contraction in depolarized rat uterus at 24° C. Record of isometric tension: *A*, 10^{-5} (gm./ml.) acetylcholine in sodium–Ringer solution ; *B*, depolarization by calcium-free potassium sulphate–Ringer solution ; contraction followed by complete relaxation ; *C*, 2·4 m*M* calcium chloride ; *D*, 2·4 m*M* calcium chloride + 10^{-5} acetylcholine. Between *B* and *C*, 105 min. *W*, washing

The findings that the effects of acetylcholine in depolarized smooth muscle require calcium ions, that calcium ions contract the depolarized muscle and that acetylcholine increases the uptake of calcium ions by smooth muscle[2] make it tempting to assume that the contractions produced by acetylcholine are due to an increase in uptake of calcium; but the above experiment showing that tensions due to acetylcholine can exceed those obtainable by calcium ions alone, makes it difficult to accept this simple explanation. Nevertheless, it is conceivable that acetylcholine may affect the movement of calcium at a functional site in a manner which cannot be reproduced by the external application of calcium ions.

It has been shown for heart[3] and striated muscle[4] that depolarization contractions produced by potassium ions require calcium. This also applies to smooth muscle. When rat uterus is immersed in calcium-free sodium–Ringer and depolarization contractions are elicited intermittently by immersion of the preparation in isotonic potassium sulphate–Ringer solution, the responses decline progressively and eventually disappear. At the same time the acetylcholine contractions in sodium–Ringer solution also diminish; but their decline is slower, so that a stage is reached in which depolarization contractions are abolished while considerable acetylcholine contractions are still obtainable (Fig. 2). The effects of lack of calcium are readily reversible on addition of calcium. This experiment provides new evidence that acetylcholine can cause contractions of smooth muscle which are not mediated by depolarization.

It has been previously shown that maximal doses of acetylcholine produce less tension in depolarized than in polarized smooth muscle[1]. This raises the question whether acetylcholine acts by the same mechanism in the two cases. In both instances the effects are antagonized by small concentrations of atropine, which seems to suggest that the receptors involved are similar. Part of the increased tension developed in polarized preparations is probably due to the occurrence of conducted impulses which are abolished after depolarization. Spike discharges in smooth muscle are increased in number by acetylcholine[5], suggesting that conducted impulses may be increased.

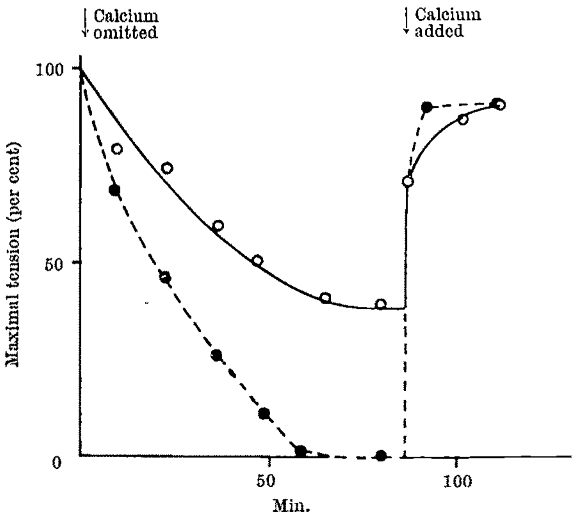

Fig. 2. Differential decline of isometric tensions produced by 10^{-4} acetylcholine (○) in sodium–Ringer solution and depolarization (immersion in isotonic potassium–Ringer solution, ●) after omission of calcium. Each point is the mean of two responses obtained from the two horns of a rat uterus, the lumens of which were opened by a longitudinal section giving sheets of approximately 1 mm. thickness. Temperature, 23° C.

It appears, however, that an additional factor is involved in the greater development of tension of polarized preparations, as may be inferred from the record shown in Fig. 3. A rat uterus horn was immersed first in calcium-containing Tyrode solution and then successively in the following calcium-free solutions : potassium–Ringer, sodium–Ringer and again potassium–Ringer. Taking into account the progressive decline due to lack of calcium, it is seen that

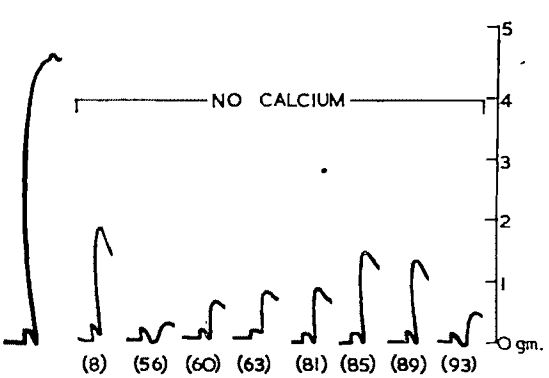

Fig. 3. Effects of acetylcholine (5 × 10^{-5}, gm./ml.) on rat uterus in calcium-free solutions during successive periods of immersion in sodium chloride–Ringer solution and potassium sulphate–Ringer solution at 23° C. Numbers within brackets denote minutes after removal of calcium chloride from the bath. Note : (1) overall decline of responses due to lack of calcium ; (2) increased responses after change from potassium–Ringer to sodium–Ringer solution ; (3) initial potentiation of response after change from sodium–Ringer to potassium–Ringer solution

not only are the acetylcholine responses increased when the preparation is changed over to sodium–Ringer, but there also is a further potentiation of the first few acetylcholine responses after re-introduction of potassium–Ringer solution. The persistence and slow decay of this effect suggests that immersion in sodium–Ringer solution has produced some persistent, slowly decaying alteration in the smooth muscle cell which improves the response to acetylcholine.

To summarize : (1) Calcium ions in low concentrations cause development of tension in the depolarized rat uterus muscle. The tensions produced are submaximal but can be further increased by the application of acetylcholine. (2) Contractions induced by depolarization and by acetylcholine are both dependent on calcium. However, depolarization responses decline more rapidly in the absence of calcium than acetylcholine responses, so that a stage can be reached when acetylcholine is effective but depolarization by isotonic potassium sulphate is ineffective. (3) Acetylcholine causes greater development of tension in polarized than in depolarized smooth muscle preparations. This difference is probably due partly to conducted impulses in the polarized muscle and partly to some other factor, so far unexplained.

Influence of Changes of Blood Volume on the Concentration of Aldosterone in Peripheral Plasma of Intact Unanæsthetized Dogs

Investigations by F. C. Bartter *et al.* and by G. Farrell and his collaborators[1] on the regulation mechanism of aldosterone secretion have indicated a close relationship between blood volume and the production-rate of the hormone aldosterone. The effect of changes of fluid volume has been studied by these authors, measuring the aldosterone secreted in the urine or in the adrenal venous blood. None of these methods tells anything definite about variations of the concentration of hormone in the peripheral blood. As the action of the hormone in the organism is supposed to be closely dependent on the concentration in peripheral blood, it is of great interest to follow these concentrations directly, and information about the latency of variations may prove to be useful for the elucidation of the nature of regulation of the level of the hormone.

The double-isotope derivative method for determination of cortisol described by Bojesen[2] has been refined to the low level of aldosterone in peripheral plasma[3]. Using this method, we have examined the effect of bleeding, blood transfusion, infusion of a dog Ringer's solution, and infusion of dog Ringer's solution made up with 5 per cent dextran, on the concentration of aldosterone (extractable with chloroform) in the peripheral plasma of dogs. Docile dogs were selected for the experiments, which lasted about 1½ hr., during which the animals were lying on a table. Being accustomed to this, the animals were not agitated during the experiments. They had been fed with a diet low in salt (pork meat, potatoes, distilled water) for more than a week before the experiments were carried out. In all cases, a sample of blood, about 30 ml., was taken from the saphenous vein or the femoral artery just before the treatment to be studied was given. This was finished within 2–5 min. from zero time. Blood samples were then collected at intervals of about 20 min. during 1 hr. In the bleeding experiments, the blood was collected from the femoral artery into a sterilized transfusion bottle, using citrate as an anticoagulant. The blood was given to the same dog through the saphenous vein 3–4 days later, in the transfusion experiment. The dog Ringer's solution employed has been described previously[4] and is a solution imitating an ultrafiltrate of the plasma of normal dogs. The dextran used was 'Dextran 150' (Pharmacia, Copenhagen). As it was found in preliminary experiments that the dog Ringer–dextran solution, when infused, had the same depressing effect on the aldosterone-level as had the blood transfusion, every blood sample was simultaneously compensated for by injection of an amount of Ringer–dextran solution equal to the amount of plasma taken from the animal. Besides the experiments mentioned, in which the fluid volumes taken from or given to the dogs were 200–250 ml., control experiments were carried out, in which no change of the blood volume of the animal was induced, the samples being compensated for by dog Ringer–dextran solution as mentioned.

Table 1. Response of Plasma Aldosterone to Induced Changes in the Blood Volume by Different Means

The figures in parentheses indicate the interval of time between the induced change in blood volume and the collection of the blood sample. With the amount of plasma analysed (15 ml.), 5 ngm. per 100 ml. is the lower limit of sensitivity of the method

Type of experiment	Dog	Aldosterone in plasma ngm. per 100 ml. (time, min.)			
		1	2	3	4
Bleeding	*C*, ♀, 22 kgm.	33 (0)	162 (22)	156 (39)	236 (72)
	M, ♀, 18 kgm.	7 (0)	29 (13)	31 (30)	23 (62)
	J, ♀, 17 kgm.	31 (0)	41 (16)	51 (38)	59 (64)
Blood transfusion	*C*	40 (0)	26 (15)	14 (30)	10 (50)
	M	40 (0)	16 (22)	23 (42)	13 (67)
	A, ♀, 15 kgm.	51 (0)	14 (30)	10 (43)	8 (60)
Dog Ringer's solution	*M*	45 (0)	19 (20)	11 (50)	17 (65)
	M	46 (0)	44 (25)	16 (50)	25 (65)
	M	28 (0)	18 (22)	12 (45)	17 (65)
Dog Ringer–dextran	*M*	100 (0)	39 (22)	16 (37)	20 (58)
	J	55 (0)	14 (14)	12 (29)	5 (45)
Control	*J*	5 (0)	5 (21)	13 (56)	8 (82)
	J	17 (0)	20 (18)	17 (33)	19 (58)

The results (Table 1) are as might be expected from the previous work by others[1]. The very marked difference between the level of aldosterone in the first and the second blood samples except in the control experiments clearly shows that the blood volume is directly related to the level of aldosterone by means of a very rapid mechanism. As the rates of elimination and production will both influence the level in the peripheral plasma, the results do not lead to a final conclusion concerning the latencies of the regulation of the rate of production. In the case of bleeding, a comparison with the results obtained in similar experiments with the collection of adrenal venous blood suggest, however, that decreased elimination is not a main factor. In the case of transfusion and infusion experiments with dog Ringer–dextran, the steep slope of the plasma curve indicates that if the rate of elimination were a main factor, the increase of rate required is too great to be likely. Therefore our results suggest that the mechanism by which aldosterone secretion is regulated operates with a latency of a few minutes in relation to changes in the blood volume.

Œstrogen Antagonisms: 19-Norprogesterone and 18,19-Dinortestosterone as Œstrone Antagonists

CLEAVAGE of the angular methyl group at carbon-10 of the testosterone molecule results in a compound that is much more potent than the parent as an œstrogen antagonist (unpublished work) and myotropic agent[1], but not as an androgen[1]. Since 19-norprogesterone has been known as a potent progestational agent for some years[2] and 18,19-dinortestosterone has recently been synthesized by Dr. W. F. Johns, of the Division of Chemical Research, G. D. Searle and Co., these two materials have been examined as antagonists of œstrone-induced vaginal smear changes in spayed mice.

The assay will be described in detail elsewhere (unpublished work). Spayed, adult, female mice were selected from a colony and injected with a total dose of 2 μgm. of œstrone, given in four equal, daily, subcutaneous injections over a 4-day period. Vaginal smears were taken on the afternoon of day 5 and morning of day 6, and were scored as positive if no leucocytes were present[3]. The standard dose of œstrone produced 80–100 per cent positive responses in various tests with 10–15 mice in a group. Comparisons between and among compounds were made at the dose-level that was estimated to produce a 50 per cent depression in this response.

Table 1. EFFECTS OF PROGESTERONE, 19-NORPROGESTERONE AND 18,19-DINORTESTOSTERONE AS ANTAGONISTS OF THE VAGINAL SMEAR EFFECTS OF 2 μGM. OF ŒSTRONE

Dose: œstrone 2 μgm. + other steroid	Progesterone: No.	Progesterone: No. positive	Progesterone: Per cent positive	19-Norprogesterone: No.	19-Norprogesterone: No. positive	19-Norprogesterone: Per cent positive	18,19-Dinortestosterone: No.	18,19-Dinortestosterone: No. positive	18,19-Dinortestosterone: Per cent positive
0	33	30	91	29	28	97	14	14	100
1				13	12	92			
3				13	11	85			
10	28	21	75	27	13	48			
30	35	30	86	26	8	31	14	12	86
100	36	19	53	14	1	7	14	14	100
300	25	12	47	14	0	0	15	15	100
1,000	17	0	0				14	14	100

Approximate ED_{50}: progesterone, 180 μgm.; 19-norprogesterone, 14 μgm.; 18,19-dinortestosterone, >1,000 μgm.

19-Norprogesterone is some thirteen times more potent than progesterone as an antagonist of the vaginal smear effects of œstrone (Table 1). 18,19-Dinortestosterone had no effect on the proportion of positive responses at doses up to 1,000 μgm. (This dose of 18,19-dinortestosterone produced slight but significant inhibition of the uterine growth stimulated in immature mice by 0·3 μgm. of œstrone.)

The high potency of 19-norprogesterone correlated well with previous results in which the 19-nor-configuration was more potent than the natural form (unpublished work). The absence of activity of 18,19-dinortestosterone is of particular interest; cleavage of the angular methyl group at carbon 10 increases the potency of testosterone (80–170 per cent, unpublished work) as an œstrone antagonist, whereas with the further cleavage of the methyl group at carbon 13 activity is largely lost.

RADIOBIOLOGY

Lead-210 in Some Human and Animal Tissues

IN two recent publications[1,2] measurements have been reported of the levels of lead-210 (radium-*D*) in the bones of non-occupationally exposed American subjects. In the present communication similar findings are reported for some human and animal bone and liver specimens from Great Britain.

Six samples of bone, obtained from subjects who had died of malignant disease, were analysed for both total lead and lead-210. The specimens were dry ashed at 470–500° C., using lead-free concentrated nitric acid as an ashing aid. After solution of the ash in lead-free hydrochloric acid, lead was extracted with diethyl-ammonium diethyl-dithiocarbamate at *p*H 0·1 and then estimated colorimetrically using dithizone, lead-210 being estimated afterwards by low-background beta counting of the daughter bismuth-210, which was separated from lead with cupferron (to be published). The results are given in Table 1. It will be seen that the mean stable lead concentration was 6·3 μgm./gm. bone, in good agreement with the value of 6·6 μgm./gm. found by

Table 1

Tissue	Stable lead (μgm./gm. wet bone)	Tead-210 (picocurie/gm. wet bone)
Human vertebra	6·8	0·026
Human vertebra	4·4	0·029
Human vertebra	8·9	0·025
Human vertebra	8·7	0·034
Human vertebra	4·0	0·022
Human tibia	4·5	0·021
Mean	6·3	0·026
Ox bone (shaft)	3·8	0·26
Ox bone (shaft)	2·4	0·24
Mean	3·1	0·25

Tipton[3]. The mean lead-210 concentration of 0·026 picocurie/gm. of bone is comparable with the values found by Hursh[1] at Rochester, and Holtzman[2] at Argonne, of 0·015 and 0·040 picocurie/gm. respectively.

At the same time, measurements have been carried out to determine the nature of the α-radioactivity previously reported[4] in the liver of seven non-occupationally exposed individuals at levels of the order of 0·34 picocurie/gm. ash, equivalent to about 0·003 picocurie/gm. tissue. Using an improved version of our sensitive α-spectrometer (ref. 5, and to be published), α-spectra have been obtained of the ashed liver of two other unexposed individuals (both malignant cases, as were also the earlier subjects). These show at least 80 per cent of the activity in a single spectral line at approximately 5·3 MeV., corresponding to polonium-210. One of these spectra is shown in Fig. 1. Since it is to be expected that most of the polonium present in the original sample would be volatilized during ashing, the subsequent observation of polonium-210 in the ash is presumably indicative of the presence of its parent lead-210. Although these identifications have so far been made for two individuals only, it seems reasonable to suppose that some 80 per cent or more of the total α-activity previously reported for the larger group of liver samples (that is, approximately 0·0025 picocurie/gm. of wet tissue) was also due to the presence of lead-210.

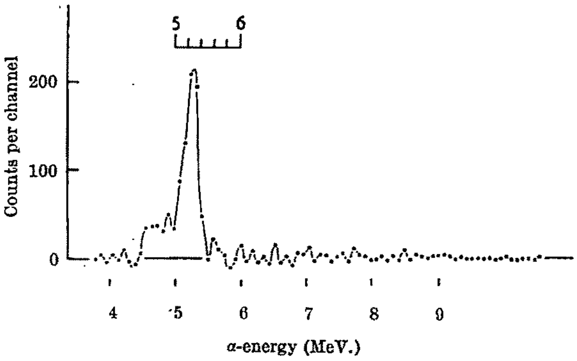

Fig. 1. α-Particle spectrum of a sample of human liver ash

We have also measured the total lead and lead-210 contents of two samples of ox bone. The results, included in Table 1, indicate that the lead-210 contents are some ten times higher than for humans, although the total lead contents of ox bone are lower by a factor of two. By means of α-spectroscopy, supported by observations of the rate of growth of total α-activity after ashing, the lead-210 content of a sample of ox liver was found to be approximately 0·05 picocurie/gm. of tissue, some twenty times greater than the value reported above for human beings. It appears that the relatively high levels of lead-210 in the ox may be attributable to the previously reported occurrence of this nuclide on foliage[6].

We wish to acknowledge the support and encouragement of Prof. W. V. Mayneord in this work, and our thanks are also due to Dr. W. Anderson and Mr. J. O. Crookall for helpful discussion. We are indebted to Dr. J. P. M. Bensted of this Department, and to Dr. N. F. C. Gowing, director of the Department of Pathology, Royal Marsden Hospital, for providing post-mortem material. Financial support for one of us (Z. S. J.) was provided by the International Atomic Energy Agency.

Incorporation of Phosphorus-32 into Adenosine Triphosphate of Adrenal Chromaffin Granules

THE discovery by Hillarp and his colleagues[1] of the presence of large amounts of adenosine triphosphate (ATP) in the adrenal medulla has led to speculations on its role in the storage and retention of catechol amines in this tissue. It has been shown that the amines are stored in cell organelles, the chromaffin granules, which are distinct from the mitochondria ; they can be separated from the latter by centrifugation over a density gradient[2]. This has made it possible to establish that ATP occurs in a high concentration in the sites of storage of the catechol amines, in stoichiometric amounts in relation to the amines present.

It is known from work on many different types of cells that the mitochondrial ATP is rapidly turned over ; but it is not known if the same holds for the ATP in the chromaffin granules. Either the main function of the ATP is to act here as the anion that holds the catechol bases in the storage position, or it serves as an energy donor in maintaining the high concentration of amine in this site against a diffusion gradient. Thus, some insight into the function of the ATP might be gained by a study of the incorporation of phosphorus-32 into the ATP of chromaffin granules, as compared to that in the mitochondria.

Animals received 0·5–1·0 mc.^{32}P/kgm. body-weight 0·5–2 hr. before death. The rats were killed by decapitation and the adrenals were rapidly removed, adherent fat was dissected away and the glands were dropped into 0·3 *M* sucrose at 0°. The dog was anæsthetized with pentobarbitone before death and the cats were killed by cervical fracture. The mitochondria and chromaffin granules were separated by density-gradient centrifugation and deproteinized with trichloroacetic acid, which was then removed with ether. ATP in the granules was measured by the firefly method[3] and its phosphorus-32 activity was obtained after chemical hydrolysis. Good agreement was found between chemical and firefly estimations, a result which suggests that the predominant nucleotide was ATP. ATP in the mitochondria either was determined chemically as inorganic phosphate liberated by 15 min. hydrolysis in *N* hydrochloric acid at 100°, or the nucleotides were separated on 'Dowex' columns[4], the phosphorus-32 was counted and the concentration determined by the firefly method.

Table 1. INCORPORATION OF PHOSPHORUS-32 INTO ADRENAL MITOCHONDRIA AND CHROMAFFIN GRANULES

Species	Time after injection (hr.)	Specific activity*	
		Mitochondria	Granules
Cat	0·5	285	< 5
	2·0	465	—
Rat	1·0	65	< 5
	1·0	78	< 5
	1·0	66	13·5

* Specific activity as counts/min./μgm. phosphorus.

It will be observed (Table 1) that in both the cat and the rat the specific activity of granular ATP was very much less than that of the mitochondrial ATP. With these two species the adrenal cortex was not separated from the medulla so that the mitochondrial fraction represented material from two different parts of the gland. Since these could have different turnovers of ATP, an experiment was performed with a dog, with which species separation of the two regions of the gland could be achieved before isolation of the mitochondria. Although Spiro and Ball[5] have reported that the respiratory enzymes in the cortex of bovine adrenals are several times more active than those in the medulla, at 1 hr. after administration of phosphorus-32 to the dog, the specific activity of the ATP (separated on 'Dowex') of the cortex was only 50 per cent greater than that of the medullary mitochondria. Therefore, it seemed unlikely that the large differences in specific activity of ATP between cat and rat mitochondria and granules was due to ATP of high specific activity from the cortical mitochondria exaggerating a very low activity from the medullary mitochondria.

The presence of ATP in different cell compartments with different turnovers has been discussed by Chance[6], with reference to mitochondria and cytoplasm, and a distinction between nuclear and cytoplasmic ATP metabolism has also been observed (Ord, M. G., and Stocken, L. A., unpublished work). The low uptake of phosphorus-32 in the granule fraction could be readily understood if we assume that the ATP is functioning in the granules as a relatively inert binding anion for the catechol amines, rather than as an energy donor concerned with maintenance of their concentration. It is hoped to obtain further evidence on this point by a study of the uptake of phosphorus-32 into ATP during the restoration of catechol amines after depletion of the granules.

This work was performed during the tenure of a Special Traineeship Award from the National Institute of Neurological Diseases and Blindness to one of us (W. H. P.).

PATHOLOGY

Production of Pyrogenic Substances by Extracts of Delayed Hypersensitive Cells mixed with Antigen *in vitro*

MANY published experiments on the passive transfer by cells of hypersensitivity undoubtedly indicate that the mechanism of delayed (tuberculin) hypersensitivity is based on a reaction of hypersensitive cells with antigen. In previous work I have demonstrated that, on incubation of delayed hypersensitive cells with antigen *in vitro*, substances are formed imitating manifestations of delayed hypersensitivity, namely, fever and inflammation of the skin[1]. Simultaneously with the formation of pyrogenic substances, the cells are desensitized, that is, they lose the ability to transfer passive hypersensitivity[2].

The question whether a similar reaction (formation of pyrogenic substances) could be evoked when mixing and incubating cell-free extracts of hypersensitive cells with specific antigen has now been investigated.

Sensitization of the animals (guinea pigs, rabbits), preparation of cell suspensions from spleen and lymph nodes, antigen used (2 μgm. purified protein derivate or 0·5 L_f purified diphtheria toxoid), and the method of evaluation of the fever reactions have been described in detail elsewhere[1]. A positive reaction is manifested by a short monophasic fever beginning usually within 15 min. and culminating in 30 min. after injection of the substance tested to normal, non-hypersensitive animals.

Cell-free extracts were prepared either by repeated (8–10 times) freezing and thawing or by ultrasonic radiation; active substances are released even on 24-hr. storage of hypersensitive cells in Hanks's solution at + 4° C. In the preparation of the extracts the decrease of the cell count was followed, and also the loss of staining characters as viable cells, as well as the increase of protein substances in the supernatant fluid.

A typical experiment is reported in Table 1. Neither the cell-free extract of hypersensitive cells nor the antigen is found to be pyrogenic. The mixture of these substances is pyrogenic, irrespective of the incubation period; pyrogenicity is developed even when the antigen and the cell-free extract are mixed and injected immediately to the test animals. It is evident from Table 1 that not even a 10-fold quantity of antigen or 5-fold amount of cell-free extract is capable of evoking pyrogenic reaction by itself. The same results were obtained in a number of experiments with rabbits and when mixing extracts

	various	0·1 −0·2 −0·2 0

of diphtheria toxoid hypersensitive cells with the specific antigen. Extracts of normal cells mixed with antigen or extracts of hypersensitive cells mixed with the non-specific antigen yield completely negative results.

The effective substance (factor giving rise to pyrogenicity on mixing with antigen) can be stored in the frozen state. Its physical and biochemical properties and further biological effects are under investigation.

A few observations can be found in the literature concerning the possibility of passive transfer of delayed hypersensitivity by cell-free extracts in laboratory animals[3] and especially in man (so-called 'transfer factor')[4]. The appearance of pyrogenicity (as a manifestation of delayed systemic hypersensitivity)[5] in the reaction of hypersensitive cell extracts with antigen *in vitro* is in agreement with the experiments reported.

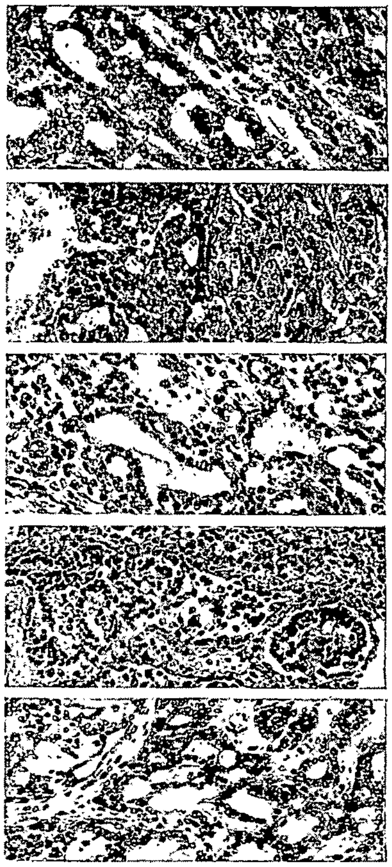
Induction of Mammary Carcinoma in Hypophysectomized Rats treated with 3-Methylcholanthrene, Œstradiol-17β, Progesterone and Growth Hormone

THE rapid induction of mammary carcinomas in rats treated by intra-gastric administration of 3-methylcholanthrene has been described by Huggins, Briziarelli and Sutton[1]. It was afterwards shown by Huggins, Grand and Brillantes[2] that the physiological state of the mammary tree was critical in the development of such tumours, and they were unable to induce mammary carcinomas in hypophysectomized rats. The present report describes the induction of mammary carcinomas in hypophysectomized rats which were treated intra-gastrically with 3-methylcholanthrene and in which partial replacement therapy was attempted with œstradiol-17β, progesterone, and growth hormone.



Figs. 1–5. Photomicrographs of tumours from rats 1–5 respectively. (Hæmotoxylin and eosin. × 135)

The pituitaries of female Sprague–Dawley rats were removed when they were 50 days old, when they weighed between 150 and 170 gm. Treatment was begun 13 days after hypophysectomy according to the following scheme.

(1) Œstradiol-17β, 1 μgm. and progesterone, 4 mgm. in 0·2 ml. sesame oil subcutaneously daily for 6 days every week.

(2) 3-Methylcholanthrene, 10 mgm. dissolved in 1 ml. sesame oil, intra-gastrically, once weekly.

Table 1

		Rat 1	Rat 2	Rat 3	Rat 4	Rat 5	Rat 6

Total dose of growth hormone	(mgm.)	161	224	282	298	398	498
Duration of treatment	(days)	141	165	186	191	220	249
Incubation period	(days)	102	147	122	170	184	220
Site of tumours		5 R., 3 L.	1 R.	2 L., 3 L.	2 L.	3 R., 4 L.	4 L.
Size of tumours at death	(mm.)	15 × 15 × 10 10 × 10 × 5	15 × 15 × 10	6 × 6 × 4 3 × 3 × 2	15 × 15 × 3	15 × 15 × 15 40 × 40 × 30	10 × 7 × 3
Nature of tumours		Adeno-carcinoma	Adeno-carcinoma	Adeno-carcinoma	Necrotic adeno-carcinoma	Adenocarcinoma Sarcoma	Sub-epidermal basal cell tumour of skin

(3) Bovine growth hormone, 0·5 mgm. in 1 ml. saline daily for 6 days every week, rising to 1 mgm. then 2, then 3 and finally 4 mgm./rat/day after intervals of 48, 31, 35 and 36 days respectively.

Mammary gland tumours developed in five rats out of nine. Histologically each tumour had the structure of an adenocarcinoma with some areas of comparative anaplasia. Nuclei were small, and regular in size and shape. One tumour, in rat No. 4, was almost entirely necrotic. In addition to its mammary gland tumour, rat No. 5 developed a spindle-celled sarcoma which grew rapidly; and rat No. 6 developed a sub-epidermal basal cell tumour of skin but no mammary tumour. Relevant data concerning these rats are given in Table 1 and illustrations of the mammary tumours in Figs. 1–5.

It is evident that partial replacement therapy with œstradiol, progesterone and growth hormone, as in the present experiments, permits hypophysectomized rats to develop mammary carcinomas following the administration of methylcholanthrene. This is in keeping with experiments of Nandi and Bern[3] who found that the development of hyperplastic mammary nodules to carcinomas in mice, required the presence of steroids together with either growth hormone or prolactin from the pituitary; and of Kim and Furth[4] who found that growth of mammary carcinomas in rats, stopped by hypophysectomy, could be restarted by the implantation of pituitary tumours known to secrete mammotrophin.

I am grateful to Dr. Charles Huggins and to Dr. Dwight Ingle for permission and encouragement in carrying out these experiments, and to the Endocrinology Study Section of the National Institutes of Health, Bethesda, Maryland, for the gift of growth hormone. The work was supported by a grant (*C*–2213(*C*6)) from the U.S. Public Health Service.

HÆMATOLOGY

Identity of the α-Chains of the Minor Human Hæmoglobin Components A_2 and A_2' with the α-Chains of Human Hæmoglobin *A* and *F*

The occurrence of a minor hæmoglobin component (A_2' or B_2), which is related to the well-known hæmoglobin fraction A_2, has recently been described[1,2]. This variant, found in families of a Negro community of James Island, is characterized by a very low mobility at an alkaline *p*H. The electrophoretic pattern (at *p*H 8·8) of the hæmoglobin of a person heterozygous for this abnormality, shows a major hæmoglobin fraction (A_0), the fast moving fraction (A_1), the slow moving hæmoglobin A_2, and the hæmoglobin A_2' with a still lower mobility. The hæmoglobin A_2 and hæmoglobin-A_2' are present in equal amounts (0·8–1·2 per cent), the sum of both being equal to the percentage of hæmoglobin A_2 present in the blood of a normal individual. The hæmoglobin A_2' has also been demonstrated in cases with sickle cell trait[2], indicating that the two abnormalities ('double A_2 spot' and 'the presence of the abnormal hæmoglobin *S*') are controlled by a different pair of alleles. In some cases of thalassæmia trait both hæmoglobin A_2 fractions were found to be increased by a factor of two[1,2], the 'double A_2 spot' being contributed by one parent and the thalassæmia trait by the other parent.

The abnormal hæmoglobin A_2' is not rare in the Negro population of the State of Georgia. In the course of a search for hæmoglobin abnormalities of some 300 cases, using the starch gel electrophoretic technique[3,4], the double A_2 spot abnormality was found in members of at least eight families. In all cases the relative amounts of hæmoglobin A_2 as well as of hæmoglobin A_2' were about 1 per cent each (estimated with CMC chromatography[5]). In two cord blood hæmoglobin samples minor amounts (0·2–0·5 per cent) of these two fractions were demonstrable. The occurrence of hæmoglobin A_2' in cases with known hæmoglobin abnormalities (including thalassæmia) has not yet been recorded in our investigations.

Since a close relationship between the hæmoglobin A_2 and the hæmoglobin A_2' seems likely, a study of possible identical structural abnormalities was undertaken. In this communication we report part of the results of this work, namely, some hybridization experiments carried out in order to demonstrate the possible identity of the α-chains of the two minor hæmoglobin components with the α-chains of normal hæmoglobin *A* and hæmoglobin *F*. Large quantities of hæmoglobin A_2 and hæmoglobin A_2' were prepared by CMC-chromatography[5,6] using a 30 cm. × 3 cm. column and 0·01 *M* phosphate buffers of *p*H values ranging from 7·3 to 7·9 as eluting solvents. The dilute hæmoglobin solutions obtained after elution were concentrated on a small CMC column[6] and finally dialysed against distilled water. Small amounts of these components (10–20 mgm.) were mixed with equal amounts of Bart's hæmoglobin, prepared from the blood of cases described before[7]. The mixtures were dialysed at 4° C. against 0·1 *M* sodium acetate buffer (*p*H 5·0) for 36 hr. followed by dialysis for 36 hr. with a 0·01 *M* phosphate buffer of *p*H 6·8. Chromatographic separations of these mixtures before and after hybridization were carried out as described before[4–6]. The results obtained are presented in Fig. 1. In both control experiments (Bart's hæmoglobin + hæmoglobin A_2 and Bart's hæmoglobin + hæmoglobin A_2') the two major fractions are present while minute amounts of hæmoglobin *A* (and also of hæmoglobin A_2 in the mixture of Bart's hæmoglobin + hæmoglobin A_2') as impurities were demonstrable. After hybridization, however, considerable amounts of a hæmoglobin fraction were found, which showed the same mobility in CMC-chromatography as hæmoglobin *F*. The fœtal character of this component was proved by its high resistance towards alkali[6] and by its ultra-violet spectral absorption. It seems, therefore, that fœtal hæmoglobin is formed when hæmoglobin A_2 as well as hæmoglobin A_2' is hybridized with Bart's hæmoglobin. Since both hæmoglobin A_2 and hæmoglobin A_2' are composed of two different polypeptide chains (α- and δ-chains) with chromatographic properties (as tested on 'Amberlite *IRC*' 50 (ref. 4) similar to the α- and the β-chains of normal human hæmoglobin *A*,

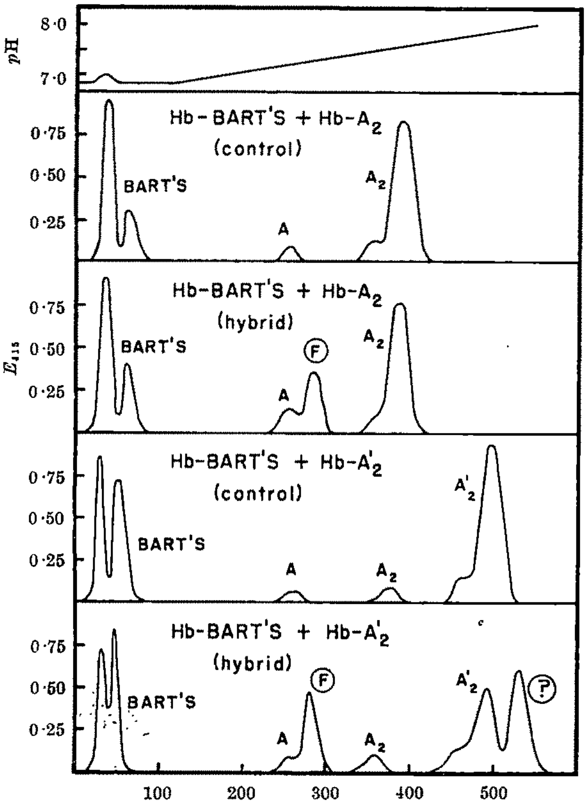

Fig. 1. Chromatographic separation on carboxymethyl-cellulose of mixtures of hæmoglobin A_2 (Hb-A_2) or hæmoglobin A_2' (Hb-A_2') and of Bart's hæmoglobin before and after hybrid formation

and since Bart's hæmoglobin consists solely of the γ-chains of hæmoglobin-*F* the following equations seem probable :

$$\alpha_2^A\delta_2 + \gamma_4^F = \alpha_2^A\delta_2 + \gamma_4^F + \alpha_2^A\gamma_2^F + \delta_4 \qquad (1)$$

$$\alpha_2^A\delta_2' + \gamma_4^F = \alpha_2^A\delta_2' + \gamma_4^F + \alpha_2^A\gamma_2^F + \delta_4' \qquad (2)$$

It thus seems probable that the α-chains of hæmoglobin A_2 and hæmoglobin A_2' are identical with the α-chain found in hæmoglobin *F* and hæmoglobin *A* [8] since the α-chains of hæmoglobin A_2 and hæmoglobin A_2' produced fœtal hæmoglobin after transfer of chain components with Bart's hæmoglobin by the hybridization technique. The components δ_4 and δ_4' formed during hybrid formation were not definitely recorded in our chromatographic experiments. It may be that both fractions possess chromatographic mobilities similar to that of hæmoglobin *H* ($\beta_4{}^A$), which is indistinguishable from Bart's hæmoglobin under our experimental conditions. It is also possible that the δ_4 component is eluted at the same *p*H as is hæmoglobin A_2 and the δ_4' component at an elution *p*H value slightly higher than found for hæmoglobin A_2' (Fig. 1). Further work, however, was not possible because of lack of material.

Our results support the hypothesis that possible structural differences between both minor hæmoglobin components and hæmoglobin *A* and between the two minor hæmoglobin fractions itself must lie in the δ-chains of the proteins.

Full extension of our results of differences between these two components and normal human hæmoglobin *A* will be given elsewhere. This work was supported in part by Public Health Service Research Grant No. *H*–5168 from the National Heart Institute, Public Health Service.

Note added in proof. Since this article was submitted, we have found a homozygous Hb-A_2' or (Hb-B_2) carrier with 2·1 per cent Hb-A_2' and no Hb-A_2.

CYTOLOGY

Aggregation of Protein Particles in Tumour Cells

IN the cytoplasm of the cells of some tumours (Ehrlich ascites tumour, Yoshida ascites tumour, Walker carcinoma, hepatoma of the rat and human malignant lymphogranuloma) a form of dispersion of the ribosomes has been seen[1–3] at the electron microscope described[4–6] as 'scattered' or 'unorganized ergastoplasm'. A similar condition also occurs[3,7] during the previtellogenesis of the oocytes in some animal species (*Haliotis lamellosa*, *Paracentrotus lividus*, *Sphaerechinus granularis*, *Arbacia lixula*). While in tumour cells 'scattered ergastoplasm' persists, it is seen[8] that in the oocytes the ribosomes, after having increased and probably having undergone a transformation, aggregate during vitellogenesis to make yolk globules (Figs. 1 and 4).

It was supposed therefore that in tumour cells there might also occasionally be found formations deriving from the aggregation of protein particles. I have now shown this to be the case.

Fragments of Walker tumour of the Wistar albino rat were put for 5 hr. at room temperature (about 22° C.) in an aqueous solution of deoxyribonuclease ('Crystalline' of Light and Co., 10 mgm./ml., non-activated). At the same time controls were kept on fragments not treated with enzyme, and on fragments kept for the same time at room temperature in distilled water only. In each case the fragments were fixed in a 1 per cent solution of osmic acid (buffered by Palade's method). For observation under the optical microscope, the fragments were embedded in paraffin ; for observation in the electron microscope they were placed in a mixture of butyl and methyl methacrylate.

Preparations and observations were made at the Centre for Electron Microscopy at the University of Padua with a Siemens Elmiskop I*a* apparatus. Under the optical microscope cells notably swollen through absorption of water were observed in the preparations treated with enzyme ; in the cytoplasm of those cells of the outer layers of the sections some very evident globules of various sizes (Figs. 2, 3) of a similar character to those of the yolk of some oocytes (Fig. 1) appeared. These globules have not hitherto been found either in control preparations or, at least

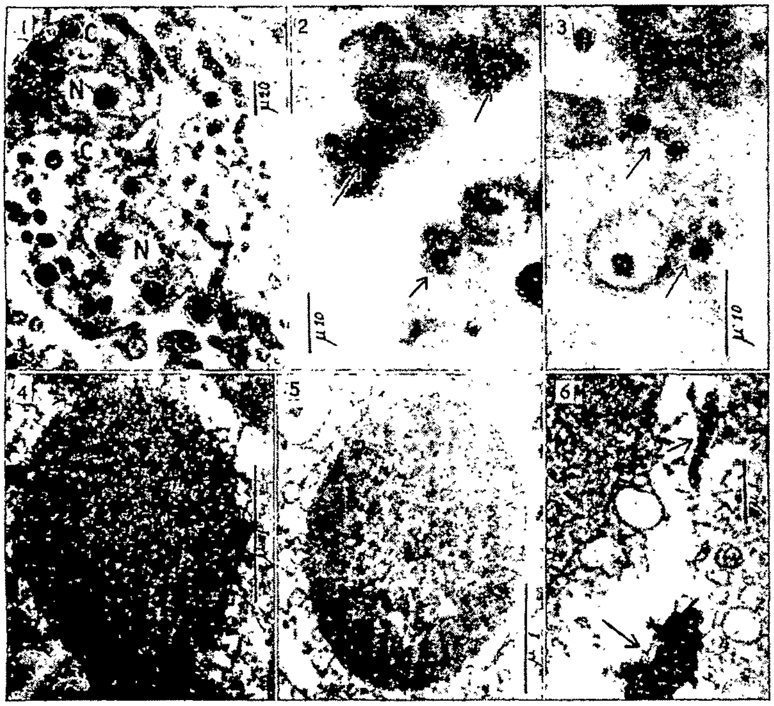

Fig. 1. Two oocytes of *Aplysia depilans*; *C*, cytoplasm with yolk globules; *N*, nuclei with nucleoli. Figs. 2 and 3. Walker tumour cells with globular formations (arrows) in a preparation treated with deoxyribonuclease. Fig. 4. Yolk globule of oocyte of *Paracentrotus lividus* derived from aggregation of granulations. Fig. 5. Globular formation of Walker tumour cell, treated with deoxyribonuclease, derived, like the yolk globule of Fig. 4, from an aggregation of granulations. Fig. 6. Portion of a Walker tumour cell kept for control in distilled water. Note the accumulations of granulations with completely irregular aspects (arrows). Figs. 1, 2 and 3, under the optical microscope; Figs. 4, 5 and 6, in the electron microscope

so far as can be seen with the optical microscope, in the cells of the more internal parts of the sections of the preparations treated with enzyme.

In the electron microscope some globular formations (Fig. 5) manifestly derived, as in the oocytes (Fig. 4), from an aggregation of granulations (ribosomes) were always seen in the cytoplasm of the cells of the tumour undergoing enzyme action. These formations, corresponding evidently to the globules seen under the optical microscope, are very variable in number and size in each cell. In the cells of the control preparation, kept in distilled water, other accumulations of granulations, but with completely irregular aspects occurred (Fig. 6).

These results must be supported by other experiments, made also in a proper isotonic and isohydrogenionic medium. It has to be established if the deoxyribonuclease, too, constitutes the only substance which can determine the process of aggregation, or rather what, like other substances, is suitable for creating the favourable conditions for this process to take place. The same result, in any event, appears to be of notable importance in connexion with: (*a*) the existence of an enormous number of unorganized ribosomes; (*b*) the possibility of obtaining their aggregation artificially as normally in the oocytes; (*c*) a new orientation for the understanding of very intense intracytoplasmatic proteic syntheses; (*d*) ascertaining of the real alteration of the tumour cells. The hypothesis[3,7] that the cellular structure, which reacts directly to the action of carcinogenic agents is the nucleolus, would seem to be more and more consistent. In fact, this, by producing the ribonucleoproteic granulations (karyoribosomes) in large quantities, would seem to provoke the transformation of the normal cell into a tumour cell. The principle would lie in a modification of the ribonucleoproteins which, through the presence of the so-called infective ribonucleic acid[9,10], would be induced to self-duplication without control.

All the alterations which, among others, include modifications in the chromosomes, hypertrophy of the Golgi bodies, and noticeable variations in the number of mitochondria[6], would derive from the incapacity of the cell to organize the ribonucleic granulations (cytoribosomes), which flow from the nucleus into the cytoplasm in enormous quantities. The uncontrolled cellular division of tumours would be but a consequence of the uncontrolled divisions of the ribosomes in the nucleus.

Finally, it should be pointed out that the result of artificial aggregation (above), from the theoretical side, is still valuable even if its realization is very rare and difficult. In this connexion the rarity with which very numerous embryos have been found in malignant tumours of the testes[11] and the ovary[12] should be emphasized; these embryos deriving probably from a kind of vitellogenesis (through aggregation of proteic particles as in the normal oocytes) within the germinative cells[7].

Distribution of Deoxyribonucleic Acid in the Cell Nucleus

THE problem discussed in this communication is the state of intermitotic chromosomes, and since deoxyribonucleic acid (DNA) is characteristic of the chromosomes it is the distribution and localization of the structure carrying DNA in the nucleus which are to be examined.

This question of distribution of DNA is of importance for the cytophotometric method of Pollister and Ris[1] measuring the relative DNA content of a Feulgen-stained nucleus. This method assumes a more or less regular distribution of DNA in the nucleus. Indeed, different investigations concerning the state of the intermitotic chromosomes have shown that they are in a very extended and hydrated state and differ in this way from the condensed and dehydrated mitotic chromosomes. According to a model first designed by Pollister[2] the swollen chromosomes nearly fill the entire nucleus. Investigations of the effects of different dehydrating agents on the nuclear structure, as we see them in the phase-contrast microscope, have confirmed this idea[3].

Recently, another interpretation of the distribution of DNA was proposed: according to Iversen's observations[4], the DNA-carrying structure is distributed in a peripheral zone of the nucleus and the remaining observed Feulgen-stained masses would be the 'nucleolus associated chromatin'. According to Iversen's illustrations, the remaining interior of the nucleus is empty and free from DNA. Similar findings have been reported by Ludford[5].

My investigations with paraffin sections fixed in various ways (non-buffered formol, Carnoy's, Stieve's, Zenker's solution, Susa mixture) have not confirmed Iverson's findings unless the preparations were dehydrated very rapidly in alcohol or were fixed in absolute methyl alcohol or formalin at pH 4·0. In normal dehydrated preparations the Feulgen-stained masses were not only on the peripheral membrane or adjacent to the nucleoli but also distributed throughout the remaining nuclear compartment. It is known that most fixing agents precipitate the proteins, especially the nucleoproteins, the intensity of the precipitation being subordinated to the pH, the destruction of the lipoids and many other factors[6]. This relationship of dehydration and the milieu can be followed with the phase-contrast microscope[3].

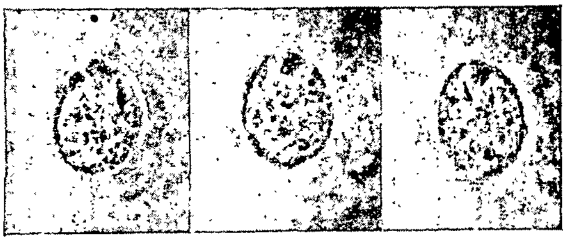

Fig. 1. Feulgen squash method, phase contrast. Nucleus from the epithelium of the colon of a female rat photographed at three different levels. Small and large chromatin granules can be seen in the nucleus

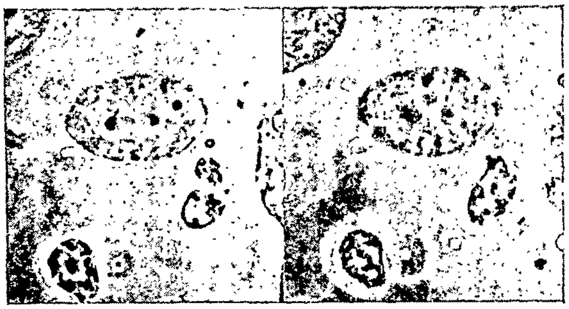

Fig. 2. Carmine acetic acid squash method, phase contrast. Nucleus from the epithelium of the small intestine of a female rat photographed at two different levels. The whole nuclear compartment is interspersed with granules. Five chromocentres are demonstrated

Squash methods, for example those described by Darlington and La Cour[7], have advantages over the paraffin section method for demonstration of the nuclear structure. With these squash methods the nuclei to be observed should not be flattened, that is, they should move freely with the current existing in the fluid between slide and cover-slip. By moving the fine adjustment one can convince oneself that, using the Feulgen-staining method[8] or the carmine acetic acid stain[9], the DNA-containing material is more or less equally distributed throughout the whole nucleus (Figs. 1 and 2). Although much chromatin accumulates directly on the inner face of the nuclear membrane, it is also often distributed without any evident order in the interior of the nucleus especially when the nucleolus also is situated in the interior. Extended research on the nuclei of different tissues has demonstrated that the distribution of the DNA-containing chromatin in the nucleus is specific with every tissue and that this specificity is lost in cancerous cells as a result of dedifferentiation[10].

These observations illustrate the fact that the DNA-carrying chromosomes are interspersed rather evenly in the nuclear compartment.

Differences in Mechanism of Staining Reaction for Mast Cells of Some Lower Vertebrates

I HAVE examined the differences in staining reactions in the mesenterial and myocardial mast cells of the viviparous Cyprinodonts *Lebistes reticulatus*, *Xiphophorus helleri* and *Xiphophorus maculatus*[1], the mesenterial mast cells of the carp *Cyprinus carpio* and in the cutaneous mast cells in precancerous skin (carcinoma planocellulare) of the lizard *Lacerta agilis*[1]. Just as in the mast cells of the mouse during the course of experiments on mucopolysaccharide reactivity after peracetic acid oxidation (Greenspan's mixture, 25° C., half an hour)[2], a change was observed in the cytoplasm of the mast cells. When the peracetic acid oxidation was followed by digestion with mucopolysaccharide-hydrolysing enzymes, various staining reactions were obtained by the methods used for mucopolysaccharides.

To permit a satisfactory comparison with the results obtained by Fullmer[3] with the mast cells in the skin, the tongue and other organs of adult *BALB/c* strain mice, I used the corresponding histological technique. Immediately after death by decapitation, excised pieces 2 mm. thick were put into aqueous neutral calcium acetate formalin at 17° C. for a period of 24 hr. (Lillie[2]). After washing and dehydration, these pieces were embedded in paraffin and sectioned at a thickness of 6μ.

The mast cells were stained in the control sections with aldehyde fuchsin, the Hale stain, the Rinehart stain and azure *A* (0·5 per cent azure *A* in aqueous 0·2 *M* phosphate buffer *p*H 4, at 25° C., half an hour). These mast cells reacted excellently, either with or without previous oxidation of tissue sections with peracetic acid. In general, the peracetic acid appeared to intensify the subsequent staining reactions. Just as in the mouse[3], if the sections were oxidized with peracetic acid and then digested with lysozyme (5 mgm. of lysozyme, Worthington ; 30 ml. of 0·2 *M* phosphate buffer, *p*H 5·3 ; 37° C. ; 24–48 hr.) or with β-glucuronidase (15 mgm. of β-glucuronidase, Nutritional Biochemicals Corp. ; 50 ml. 0·1 *M* acetate buffer, *p*H 4·5 ; 37° C. ; 24–48 hr.) only a few mast cells were affected by aldehyde fuchsin, whereas none was affected by the Hale stain. The few mast cells which reacted with the aldehyde fuchsin were only slightly stained. With azure *A*, however, the granules and the cytoplasm of the mast cells remained strongly reactive. The staining reaction appeared to be only slightly, if at all, reduced. In some cases testicular hyaluronidase (25 mgm. of testicular hyaluronidase, Nutritional Biochemicals Corp. ; 50 ml. 0·2 *M* phosphate buffer, *p*H 6 ; 37° C. ; 24–48 hr.) prevented the subsequent Hale staining reaction. If the sections were not oxidized with peracetic acid (Greenspan's mixture, 25° C., half an hour)[2] prior to the digestion step, no effect on any staining reaction was observed. By boiling for half an hour in alkaline buffer at *p*H 9, the lysozyme was inactivated, which confirms previous work by Fullmer[3]. The mast cells were found to react strongly with all stains after incubation in the usual manner with lysozyme treated in this way.

My results, like those of Fullmer[3], using mast cells of the mouse, are fully compatible with the view that after the peracetic acid oxidation both the lysozyme and the glucuronidase enzymatically remove from the mast cells a certain component which is stainable with the Hale stain and the aldehyde fuchsin, and there remains a component inducing a strong metachromasia with azure *A*. Since the inhibitors, which are not otherwise likely to alter the enzyme, prevent the effect on the staining reactions, Fullmer[3], and rightly in my opinion, maintains that the insufficient staining with the Hale stain and the aldehyde fuchsin in this case represents an uptake of basic protein by acid mucopolysaccharides, rendering these groups inaccessible to the stains. Several authors have described this type of blockage. On the basis of the reactions mentioned above, one can conclude that although, in all the three histochemical methods used, mucopolysaccharides are stained, the staining reactions of granules and other cytoplasmic components of mast cells are not equivalent at all, and probably do not form the same substance with the stain. These results are in agreement with those of Gomori[4], who had noted differences in the degree of staining of various mucopolysaccharides using various methods, and also with the fact that the periodic acid oxidation of tissue sections has been found to induce the staining of certain normally unreactive substances with aldehyde fuchsin, and to alter the susceptibility of oxytaban fibres to lysozyme, hyaluronidase and elastase.

Furthermore, I used for the staining of the mast cells of the lower vertebrates mentioned two new techniques, namely, the night-blue method[5] and tartrazine counter-staining according to the periodic acid – Schiff procedure[6].

The night-blue method is essentially the same as that reported by Hallberg[7], although for the staining of human and mammalian mastocytes by Winkelmann[5] some minor modifications were made. The mast cells of the lizard and the teleost species mentioned above showed a positive orthochromatic night-blue stain in the granules. The nuclei of mast cells were found not to stain, nor did the cytoplasm. After alcohol fixation the stain disappeared completely.

After applying tartrazine counterstaining, following the periodic acid – Schiff procedure, the granules of the mast cells of the lizard, the carp and the viviparous toothcarps stained in a different way from the other granules giving a positive periodic acid - Schiff reaction. As tartrazine, an azo derivative of 1-phenyl-5-pyrazolone-3-carboxylic acid, we used the tartrazine *O* (*C.I.* 640, from G. T. Gurr, London, S.W.6). With the tartrazine counterstaining the colour of the granules of the mast cells of the lizard, the carp and the viviparous toothcarps turned from fuchsia-red to brick-orange, whereas the other substances giving a positive periodic acid – Schiff reaction remained completely unchanged.

The night-blue method and the tartrazine counterstaining described appear to be excellent techniques also for the mast cells of the lizard, the carp and the viviparous toothcarps. The clarity of the two staining methods greatly facilitates quantitative routine estimation of the mastocyte content of tissues in lower vertebrates.

BIOLOGY

Perception of Distance in Animal Echo-Location

In a recent article[1] Nordmark fails to explain two features of the bat's ultrasonic transmissions ; one is the frequency sweep used by most species of bat employing echo-location as a means of orientation, and the other is the apparent difference between Vespertilionidae and Rhinolophidae which in fact has been shown to be a similarity[2]. As with all hypotheses related to the behaviour of animals none can be proved beyond doubt, nor can we expect any to be complete; we may, however, assume reasonable efficiency in the use of the information contained in echoes received by the bat as it relies on such information for its very livelihood.

The means, suggested by Nordmark, whereby the bat locates objects in space by listening to the note produced by two pulses arriving at the ear in quick succession is only a second-order effect (the response of the ear to the fundamental of the wave envelope is very small compared with that from the higher frequency wave), and it is unlikely that it is used directly. The bat would find no benefit from the frequency-sweep within the pulse, first observed by Griffin[3], if it used this method. Analysis of some of Griffin's records on an instantaneous spectrum analyser show the frequency modulation sweep to be nearly linear. Such a frequency sweep can provide very much more information than the simple pulse method although it is much more difficult to explain adequately[4]; and since Rhinolophidae also employ a frequency-sweep at the end of the tone transmission, it seems reasonable to believe this to be an important feature of the bat's echo-location system.

I have recently carried out some experiments in connexion with a blind guidance device which have served to confirm my beliefs. Both a pulse and a frequency-modulation echo-location system were tried on several subjects who had no knowledge whatsoever of the systems being tested or of the results to expect, so that they could only judge by their direct observations. Both systems used the same ultrasonic transducers which were capable of operating over a frequency band of 20 kc./s. centred on 50 kc./s. The transmitted energy was sufficient to render background noise insignificant at the ranges used in the tests. The pulse system employed pulses of 50 kc./s. tone lasting from between 0·1 msec. to 15 msec. which could be chosen in 5 steps and the signals presented to the ear were pulses of 3 kc./s. tone approximately. The maximum distance to an object was 15 ft., and therefore the transmission and echo overlapped in some of the tests. A 9-in. diameter metal sphere was detected at up to 10 ft. but the distance could not be determined except by the amplitude of the echo, and this with very little certainty. In some tests the transmission could not be heard by the observer; in those where it could the intensity was comparable with the largest echo experienced. Nevertheless there was little difference in the poor ability of the subject to locate an object as a result of this.

The frequency-modulation system on the other hand used a transmission which varied linearly from 60 kc./s. to 40 kc./s. at a rate which produced a difference frequency of 3 kc./s. between transmission and an echo from 15 ft. Thus the subject experienced signals covering a frequency-range of 0–3 kc./s. depending on the distance to the object. Using this system there was no difficulty in determining the distance to an object, depending only on the ability of the subject to estimate the frequency; for example, an object at 10 ft. would produce an echo at the subject's ear corresponding to an interrupted 2 kc./s. tone. With such a system even fine wires of only 1 mm. diameter could be detected with reasonable ease. This was quite impossible with the pulse system.

The conclusion drawn from these tests was that the effect described by Nordmark is very weak compared with what can possibly be obtained from the frequency-modulation sweep. Pye has shown how such a system is possible physiologically in the bat and therefore more likely to be used[2].

[3] Griffin, D. R., *Listening in the Dark* (Yale Univ. Press, New Haven, 1958).

[4] Kay, L., *Animal Behaviour* (to be published).

THE theory of range perception in animal echo-location, recently advanced by Nordmark[1], was of great interest as I had just published a theory for bats which also depends on a frequency analysis[2].

Dr. Nordmark refers to the work of Thurlow and Small[3], who describe a time-difference tone which is heard by man when pairs of sound pulses are repeated at rates greater than 25/s. The frequency of this tone is inversely proportional to the shorter pulse-separation time, and Thurlow and Small obtained some evidence that it is a central effect, produced as a measure of the interval between two sets of sensory nerve impulses. This phenomenon thus appears to provide evidence for a central timing mechanism, originally proposed for bats by Hartridge[4] and which I had found difficult to visualize.

However, any central mechanism must be limited for very short time-intervals by the refractory period of the sensory nerve. In support of this, Thurlow and Small found that for two pulses of equal intensity the minimum interval which produced a time-difference tone was about 1 msec.; shorter intervals were only effective if a small pulse preceded a larger one[5], an improbable situation in echo-location. If the second pulse were decreased in intensity (or the first one increased) this period was progressively lengthened. Grinnell and Griffin[6] have shown that the bat's auditory system can resolve pairs of equal pulses down to a separation of 1 msec., corresponding to a very intense echo returning from 16·5 cm. But a bat feeding on flying insects, which may be taking evasive action[7], must surely be able to obtain information down to the last few centimetres.

I have therefore suggested that at close range, when the echo overlaps with the emitted pulse, the bat could obtain information from beat-notes between the two signals. The refractory period is then not involved, since different receptor cells will be excited within the cochlea. The frequency-modulated pulses of Vespertilionids will give range and directional information, while the very constant-frequency pulses of Rhinolophids will measure the Doppler shift and so indicate the relative velocity.

Möhres[8] states that accuracy of perception extends to about 50 cm. for Vespertilionids, and to at least 6·4 m. for Rhinolophids—approximately the ranges expected for beat-note operation. But Vespertilionids in flight appear to have some appreciation of objects at greater distances. Possibly location is initially achieved by the time-difference apparatus, while at close range the beat-notes are used. The latter could be much more accurate as the beat-frequency may change by 40 kc./s. over a range of 50 cm. This depends however on an equal rate of frequency change in every pulse, which has not yet been established.

The long, unmodulated pulses and low repetition-rates (less than 10/s.) of the Rhinolophids do not appear to lend themselves to time-difference measurement. Möhres has rejected such mechanisms for these bats and suggested that they obtain information from the direction and loudness of the echoes. The beat-note mechanism makes this possible by avoiding masking. The rapid vibration of the ears, by producing additional Doppler shifts, can endow them with greater directionality than their size suggests, and also allows operation under stationary conditions.

An electronic model which produces various bat-like sounds and allows one to hear the beat-notes shows that the human ear can achieve considerable precision in this form of echo-location. Preliminary tests show that time-difference tones are weak for the echoes of small objects, although this need not be so in bats. It seems that frequency modulation gives little, if any, improvement. Rectification (used for the detection of beat-notes) does appear to help, presumably by allowing the ear to use the pulse envelope component as well as the carrier. No time-difference tones can be produced with artificial Rhinolophid pulses.

The complex pulses of other echo-locating animals will not form useful beat-notes. Direct echo-delay measurement, by a process such as that indicated by the time-difference tone, appears to be the only possible mechanism for these cases at present. It is suggested that the interception of flying prey by insectivorous bats is related to the characteristically simple frequency structure of their pulses, which are thus potentially more informative. But as Dr. Nordmark states, it is not certain which properties of the echoes are actually used. Further investigation is necessary before these theories can be evaluated and some understanding of the true mechanisms can be achieved.

This work is sponsored in part by the Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Force, through its European Office.

THE frequency sweep used by some bats is unlikely to be essential for distance perception by these animals, and is possibly no more than an accidental consequence of their method of sound production. When the cricothyroid muscles of the larynx of *Eptesicus* bats are denervated the modulation is altogether absent and the frequency becomes constant at about 10 kc. Yet such bats land normally on walls and avoid obstacles of moderate size. A slight decline in performance can be attributed to the greater wave-length used and the reduced vigour of the bats as a result of the surgical operation[1].

The success of these animals even under such drastically altered conditions points to the danger of attaching too much importance to specific properties of the sounds used in estimating distance. If distance is indicated by the pitch of a tone some other facts are also more difficult to explain if one assumes that the pitch is a function both of distance and definite properties of the sounds, as Kay and Pye do, rather than only of distance, as I do. If the frequency-sweep were utilized in the way these authors suggest, each animal would have to work out its own scale for measuring distance and maintain its particular sweep characteristics under all conditions. The critical variable is the rate of change of frequency, which would have to be constant. As this is a function of the frequency-range and the duration of the sweep, each of these factors must be held constant or changed to a degree which compensates exactly any change in the other factor. Such precise and complicated mechanisms for events of a few milliseconds' duration are unknown in biology. Novick[2] and Griffin[1] give many examples of the variability of the frequency-range, rate of change and duration of the sweep. Griffin's records for the bat *Eptesicus*, for example, show clearly that the decreased pulse duration as the bat approaches an obstacle results in an increased rate of change of frequency.

The typical decrease in pulse duration will also preclude the overlap between outgoing pulse and returning echo, which a frequency-modulation method of echo-location presupposes, until the last 17 cm. or so. Pye does not take this progressive decrease into consideration and it is indeed inexplicable if an overlap is to the bat's advantage. He might possibly argue that it is only during the last 17 cm., where the time-difference mechanism may fail, that the frequency sweep acquires its importance. We have to bear in mind, though, that this distance will be covered in about 1/20 of a sec., which is the reaction time between the hearing of an echo and the turning of a bat's flight according to Griffin. The interception of flying prey can be accomplished also by insectiverous bats using a different type of pulse and therefore likely, as Pye has pointed out, to use a time-difference mechanism.

The alleged advantages of the frequency-modulation method cannot be substantiated by experiments which use instruments capable of a high degree of precision for sound production and a non-linear device instead of the ear to generate the difference tones. Nor can the failure to hear a time-difference tone under certain conditions prove anything as long as we are not given the experimental details.

As Thurlow and Small had no reason to measure the thresholds for the sweep-tone under the extreme conditions—particularly the high intensity—which would correspond to animal echo-location, we cannot use their results to decide whether their pitch phenomenon is the whole answer to the problem of distance perception or not. I have recently been able to verify though, that the sweep-tone can be heard: (*a*) when the pulse-rate is irregular; (*b*) when pulses corresponding to those of other animals are present; (*c*) when the signal/echo ratio is much greater than in earlier experiments; (*d*) when the pulse-rate is no more than 2–3 per sec. and the (long) pulses overlap, corresponding to the situation for the Rhinolophidae.

Pye has raised an important point when he asks how short the interval between pulse and echo can be without abolishing the time-difference tone. The basis of this pitch phenomenon can scarcely be that suggested by Kay, and is likely to be found in the synchronized response of the nerve to pulsed stimuli. As synchrony can be maintained up to 4,000 c.p.s., the shortest interval may be 0·25 instead of 1 msec.[3]. As Dijkgraaf[4] has shown that a bat can react to a worm held about 5 cm. from the animal's mouth, the tentative limit of just over 4 cm. for the time-difference mechanism is low enough in this case.

The maximum distance recorded at which an object was detected, 6·4 m. for a Rhinolophid bat, is more difficult to explain. A pitch of 22 c.p.s. may be slightly low to serve as a reliable sign. It is important to remember, though, that echo-locating animals probably react to change and rate of change of pitch rather than absolute pitch. Under certain conditions no sharp distinction can be made between change of pitch and change of timbre, and it may be that a slight modification of the timbre is the earliest sign in many situations. If we assume that the Rhinolophidae judge the distance by the loudness of the echo we will instead be faced with new difficulties. How, for example, can these bats judge the loudness of the echo when the interval between outgoing pulses may be as short as a few milliseconds[3] ?

It should be added that the frequency of these pulses is not quite constant and therefore unlikely to be used for estimating distance according to the Doppler principle.

Insecticide Resistance in Mosquitoes

A DETAILED study of the nature and mode of inheritance of dieldrin-resistance in a strain of *Anopheles gambiae* from the Western Sokoto region of Northern Nigeria, and of DDT-resistance in a strain of *A. sundaicus* from Indonesia has already been made and recorded[1-3]. Dieldrin-resistance in *A. gambiae* was shown to depend on a single genetic factor semi-dominant in its manifestation and imparting cross-resistance to other cyclodiene chlorinated hydrocarbons and to γ-BHC but not to DDT. DDT-resistance in *A. sundaicus* also shows a monofactorial type of inheritance, but here the factor is recessive in nature and imparts cross-resistance to DDT-analogues but not to dieldrin or to γ-BHC.

Two other dieldrin-resistant strains of *A. gambiae* have now been studied, one from Kano in Northern Nigeria[4], and one from Bobo Dioulasso in French West Africa, and an identical type of resistance to that found in the strain from Western Sokoto demonstrated. In addition, dieldrin-resistance has been studied in three other species of mosquitoes, *A. albimanus*, *A. quadrimaculatus* and *Culex fatigans*, and a single semi-dominant factor has been shown to operate in all of them. The resemblance of the resistance in the two anopheline species to that previously investigated in *A. gambiae* is enhanced by the fact that the discriminating dosages of dieldrin separating susceptibles from hybrids, and hybrids from resistants, are almost identical in both larvæ and adult tests. In the case of *C. fatigans* the discriminating dosages applicable to the adults are somewhat higher than in the anophelines. In other words, the susceptible and hybrid adults are more tolerant to the insecticide than are the adult anophelines.

Three strains of *A. quadrimaculatus*, one from Maryland, one from Florida, and one from South Carolina, United States, have been used in these investigations. From the first two, dieldrin-resistant strains have been selected which are susceptible to DDT. Attempts to select DDT-resistance from the original mixed populations have failed. The South Carolina strain is susceptible to both insecticides.

The dieldrin-resistant strain of *C. fatigans* originates from Ceylon. Attempts to select DDT-resistance from it have so far failed. The susceptible strain of this species, used for crossing with this resistant strain, is one from Malaya. Both strains are much more tolerant to DDT in the adult stage than any susceptible anophelines. In fact they appear to be as tolerant as the DDT-resistant strains of anophelines so far investigated. However, the larvæ are more susceptible to DDT than those of susceptible strains of anophelines. It would thus appear that *C. fatigans* shows a natural high tolerance to DDT in the adult stage, and that this is a characteristic of the species and does not stem from any specific factors for resistance.

The dieldrin-resistant strain of *A. albimanus* was selected from a mixed population of this species from El Salvador. Like the other dieldrin-resistant species it is susceptible to DDT. The susceptible strain of the same species used for inheritance studies originated from Panama. Selection of the original mixed El Salvador population with DDT resulted in the production of what was apparently a true DDT-resistant strain of this species. Testing this selected strain on dieldrin revealed the presence of some dieldrin-resistant individuals, and selection of it with this insecticide produced a strain which would tolerate very high dosages of both DDT and dieldrin on consecutive exposures, that is, a strain showing double resistance.

From the strain showing DDT-resistance and some dieldrin-resistant individuals has now been isolated a strain resistant to DDT and completely susceptible to dieldrin by selection from the offspring of individual females.

This isolation of three strains of the same species, one resistant to DDT but susceptible to dieldrin, one resistant to dieldrin but susceptible to DDT, and a third resistant to both insecticides, is in itself a proof that two separate genetic factors are involved. Further confirmation has come from the crossing of the DDT-resistant strain with the susceptible Panama strain and studying the mode of inheritance of DDT-resistance. A pattern of inheritance has been demonstrated almost identical with that shown in *A. sundaicus*, namely, a monofactorial type of inheritance dependent on a virtually recessive factor. It remains now to cross the DDT-resistant strain with the dieldrin-resistant to show whether the factors occur on the same chromosome (and, if so, how far apart) or on separate chromosomes, and this work is in process.

Finally, DDT-resistance has also been studied in a third anopheline species, *A. stephensi*. By comparing a resistant strain from Iraq with a susceptible strain from India and crossing them, DDT-resistance in this species has been shown to impart cross-resistance to DDT-analogues but continued susceptibility to dieldrin and γ-BHC. The inheritance pattern differs slightly from that shown by *A. sundaicus* and *A. albimanus* in that the single factor involved is semi-dominant when 24-hr. mortalities from exposures to the insecticide are considered. When, however, immediate knockdown counts after removal from the insecticide are made, the factor appears to be more recessive than dominant.

DDT-resistance in *A. stephensi* is of a comparatively low order, some 10–20 times only, and exact discrimination between the genotypes is impossible. The establishment of the monofactorial character of the inheritance of resistance in this species has been confirmed finally by a process of repeatedly back-crossing the heterozygote with the susceptible parent and exposing the offspring to a dosage of DDT which is known to eliminate susceptibles completely. The survivors have then been re-crossed with the susceptible strain and the process of selection repeated. The mortality at each stage of selection has remained more or less at the same level. It has not shown the consistent rise expected where more than one genetic factor is involved.

These investigations, then, have amply confirmed that resistance in mosquitoes is of two independent types, DDT-resistance and dieldrin-resistance. Further, they have shown that resistance is dependent on a single genetic factor, semi-dominant in the case of dieldrin-resistance and recessive or nearly so in the case of DDT-resistance, the remarkable feature being that these characteristics apply to different species in widely separated parts of the world. That the two factors can exist together in the same population of the same species is now definitely established, and should further stimulate the search for new and efficient insecticides outside the chlorinated hydrocarbon group of organic chemicals.

The details of these experiments are being prepared for separate publication.

Parental Care in a Rare Spider *Pellenes nigrociliatus* (L. Koch) var. *bilunulata* Simon

In May 1959, on a strongly sunlit slope of a roadside scarp adjacent to a pine wood in Toruń (northern Poland), about 20 specimens of snail shells (*Helicella candicans* (L.Rfv.) were found each of which was suspended high above the ground (up to 18 cm.) on plants (mostly grass) by means of a 'rope' twisted together from many spider-silk threads 1–3 cm. long. The entrance to the shell was closed by a 'curtain' made from thick spider's fabric. From time to time a horizontal slit (Fig. 1) opened in the curtain, and a pair of white-haired spider's pedipalps appeared in it (Fig. 2). It was, however, difficult to make the inhabitants of the shells come out of them, though they attacked fairly vigorously a needle brought close to the opening in the curtain.

The spiders were compelled to leave the shells by putting them on a warmed base. The spider inhabiting the shell (Fig. 3) proved to be a rarity. Dr. Jacques Denis (Anzin-Nord, France) identified it as *Pellenes nigrociliatus* (L. Koch) var. *bilunulata* Simon. According to him, until now this form has been known only as one specimen found in France (Tarn).

During June and July 1959, in the course of several trips, I found, on the same scarp, 20 more suspended shells of the same species. All specimens of spiders found were females. They were taken to the laboratory and placed in small glass terraria, with empty snail shells on the floor—the same which abounded on the scarp. Expelled from their shells, in the same way as in the first case, they were left in the terraria. Soon it was noticed that some of the spiders were attaching threads to the empty shells. Then, in absence of plants, they attached the threads to the wall of the terrarium. After suspending the shell they entered and closed the entrance with a thick curtain of spider's web. As it appeared later, they made nests in the shells. During June–July, about 10 eggs enveloped in a very thick, silky, unusually ductile fabric were found in the particular shells. The spiders hatched underwent their first moult in the shell, and only then began to leave the shells; but for a long time they would return to them.

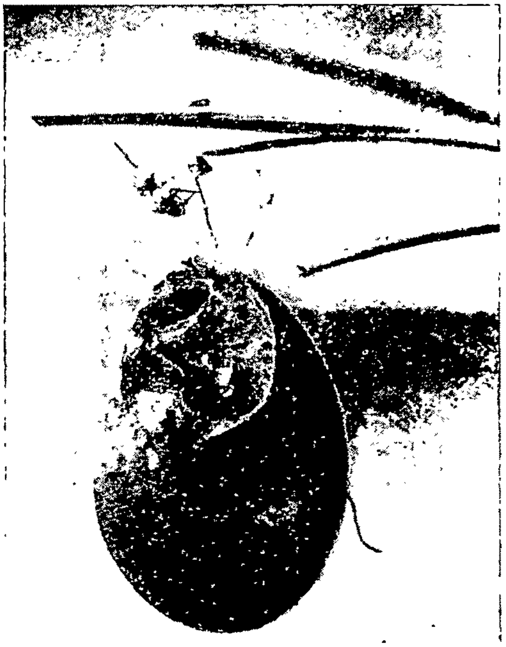

Fig. 1. Entrance to spider's 'nest' (× c. 4·7)

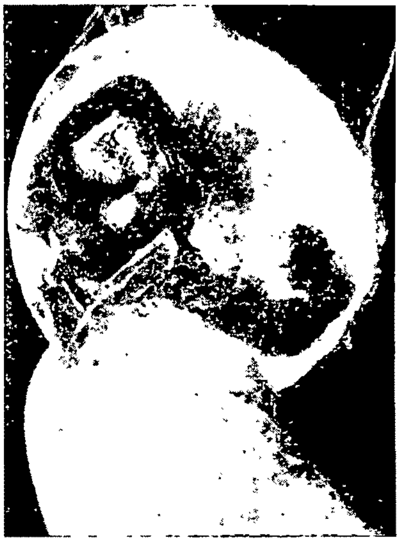

Fig. 2. The spider appearing in the 'nest' entrance (× c. 18)

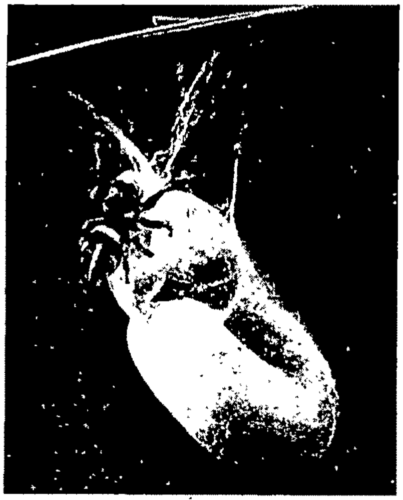

Fig. 3. The spider on the shell (× 4)

In 1959 no male was found on the scarp. During early April 1960 the scarp was searched. At that time only the earliest plants were growing and grass was still scarce. One male spider, similar to the females found before, was seen on the ground. There were, however, no suspended shells. In May the search was repeated, and 18 suspended shells with a female in each of them and eggs in some were seen.

The spiders were taken to the laboratory, where systematic observations have been conducted on the behaviour of the adults and of the young.

I am grateful to my assistant, W. Kokociński, for the photographs.

Flowering Behaviour of Vanilla

THE vines of *Vanilla planifolia* Andrews will climb to heights of 60 ft. or more, if provided with a sufficiently tall support plant. The vine must therefore be trained to a height convenient for pollination and harvesting in the commercial production of vanilla. The prevention of the natural tendency to climb is thought to enhance the production of flowers[1]. It is believed that flowering will not occur as long as the vine can climb upward[2-7]. Childers[3] suggests that "bending of vine appears to be an important factor in causing it to flower and fruit beyond the bend, which may be due to an accumulation of carbohydrates and possibly other flower-forming materials in this region of the vine".

Observations on the flowering and fruiting of *V. planifolia* have recently been made in an abandoned vanillery in western Puerto Rico, which had not been under cultivation for at least 15 years. Since the plants in this area were growing on both short and tall supports, the plants were of both a rambling and a climbing habit of growth. Both types were inspected for flowering. Five plants of the low-growing type gave a total of 65 inflorescences on horizontal and descending branches, while no evidence of flowering was observed on the few short ascending stems present. Ten vigorous, climbing plants were selected at random, and counts were made of flower spikes on ascending and descending stems. Ascending, or climbing stems had a total of 82 inflorescences, while descending stems had a total of 29 flower spikes. One plant with 18 flower spikes consisted entirely of two main branches which had grown to a height of 60 ft. and were still climbing. The majority of inflorescences occurring on ascending vines were 30–50 ft. above the ground, and were on stems that were free of bends for at least 10 ft. in either direction. The absence of flowers on the lower 30 ft. of the climbing plants suggests that a considerable amount of growth may be necessary before flowering occurs, and that flowers should not be expected to occur on the short basal stems of rambling plants.

The inflorescences on ascending vines were capable of bearing fruit, and on one plant with 27 pods all occurred on climbing stems.

These observations indicate that *Vanilla* will flower and set fruit, whether climbing or not, and that a change in the direction of growth is not necessary for flower formation.

Striate Mosaic: a New Disease of Sugar Cane

THE term 'striate mosaic' is proposed for a new disease of sugar cane found in the varieties Pindar and Q.57 in the Lower Burdekin district in north Queensland. The most obvious features are the short, fine striations which can just be separated by the naked eye. They are a lighter colour than the normal leaf blade and show first on the youngest exposed leaf and reach their best development as the leaf expands, but are difficult or impossible to find on mature and older leaves. They occur less in the region of the large vascular bundles than in the tissue between and so in the aggregate often give a marked striping effect on the younger leaves, or even a yellowing to the entire top. Severe stunting is usually associated with the striations but striations without obvious stunting have been found in Pindar.

The disease is sett-transmitted and heat treatment of the setts in water at 50° C. for 3 hr. or in air at 54° C. for 16 hr. (as used in the control of ratoon stunting disease[1]) failed to free them from the disease. Inoculations into healthy setts did not produce the disease but the striations alone or with the stunting may be transmitted by the Sein inoculation technique[2]. It spreads very slowly in the field, and the use of disease-free planting material should prevent it ever causing serious losses.

It would appear that viruses, one causing the striations and one the stunting, are responsible for the disease.

A detailed report is in course of preparation.

Moisture Conditions for testing Germination

The International Standards for Seed Testing[1] detail the requirements for assessing the viability of many species, but provide only general directions for the moisture regime to be used, namely, "For most kinds of seeds, blotters or other paper substrata should not be so wet that by pressing, a film of water forms round the finger". In soil physics terminology, these substrata would be at an indefinite suction approaching zero (that is, free water). Furthermore, the suction is not necessarily constant throughout the test, namely, "subsequent watering if any should be left to the analyst".

We have adapted simple experimental equipment[2] to determine the influence of small changes of suction at or about zero suction. Representative replicated results for three species under identical illumination, temperature, and relative humidity environments are listed in Table 1. Seeds were selected for uniformity and dusted with tetrachloro-*p*-benzoquinone to prevent fungal growth. Germination was taken as being the emergence of the radicle, instead of the "emergence and development from the seed embryo of the essential structures which for the kind of seed are indicative of its ability to develop into a normal plant under favourable conditions"[1]. If this latter definition had been used, the differences between suctions would have been more marked, since the faster germinating seeds also showed faster development; for example, after 18 hr., oats at 0 cm. suction had 1 cm. green shoots, while at 10 cm. water suction there was only an emerged radicle, these two conditions not being differentiated in Table 1.

For each of the species described in the table, and over this limited suction-range, the total number germinated after 10 days was constant. Hence the total of the four replicates at each time has been expressed as a percentage of the total final count for that species.

Table 1. Cumulative Germination expressed as Percentage of the Number of Viable Seeds obtained after 10 days of Treatment

Species	Suction cm. of water	Days of treatment 1	1½	2	2½	3	5
Avena sativa L. var. Klein (oats)	0	0	0	30	51	80	98
	2	0	0	2	15	57	93
	4	0	0	2	3	33	92
	6, 8 and 10	0	0	0	2	21	82
Medicago sativa L. (lucerne)	0	90	93	96	97	98	99
	2	70	83	96	97	98	99
	4	67	83	96	97	98	99
	6, 8 and 10	61	77	96	97	98	99
Lolium perenne L. Mansfield strain (perennial rye-grass)	0	0	0	24	39	69	95
	2	0	0	35	51	84	97
	4	0	0	37	53	91	99
	6, 8 and 10	0	0	39	65	93	99

Both oats and lucerne show a significant decrease in germination-rate on increasing the suction from 0 to 6 cm. water, while perennial rye grass showed an increase in rate over the same range.

These germination results were compared with those from the New South Wales State Department of Agriculture Seed Testing Laboratory using the same seed sample and the procedure of the International Rules[1]. The final count numbers at 10 days were identical, but the rates for 'standard' treatments varied more than those of all the suction regimes listed in Table 1. This variation can therefore be attributed to inconstancy in the moisture regime of the substrata, which under the existing standards is outside the control of the tester. In those laboratories where seed testing is infrequent, it is likely that variability will be greater than in routine testing, particularly when attempting to obtain comparable moisture conditions for seeds differing in size and shape.

It is suggested that small variations in moisture regime have been the cause of inconsistencies attributed to other factors; for example, Ahring *et al.*[3] investigated temperature differentials encountered in seed germination experiments, but as the moisture regime was not specifically controlled (it would require some form of tensiometer to detect small differences within the range 0–6 cm. water) all the detected responses cannot be attributed to a temperature factor.

Isely[4] recommends placing the Petri dishes of substrate within plastic freezer bags containing wet filter papers to saturate the atmosphere. However, this would not easily maintain any particular suction and would only minimize loss of vapour. If seeds were to be germinated on tension plates, a suction for optimal germination could be specified for each species, hence eliminating the use of various types of substrata.

ENTOMOLOGY

Termination of Diapause in *Acheta* by Urea

The rate of termination of diapause in eggs of *Acheta commodus* (Walk) has a negative temperature coefficient within the range $-16 \cdot 5$ to $+5°$ C.[1]. It has been reported by Jacobsen and Christensen[2] that the initial stages of denaturation of β-lactoglobulin by urea has a negative temperature coefficient. Accordingly, experiments have been carried out with certain denaturants, primarily urea, for evidence of any effect on diapause. The attempt was made to incorporate the chemicals into the eggs by making use of the capacity of Orthopteran eggs to take up water during their development. In *Acheta* the uptake of water occurs slightly later than the onset of diapause[3].

(1) Eggs, up to one day old, were placed on blotting paper disks previously moistened with solutions of the chemicals under test. They were then incubated, in sealed tubes, at 27 (± 0·2)° C.

Definite responses were obtained with urea. Table 1 shows that urea solutions at the strengths normally used for denaturation of protein were extremely toxic but at a concentration of 0·08 *M*, a highly significant increase occurred in the proportion of eggs that completed their development without evidence of diapause.

Table 1. PERCENTAGE OF EGGS DEVELOPING WITHOUT EVIDENCE OF DIAPAUSE AFTER EXPOSURE DURING THE PRE-DIAPAUSE STAGES TO SOLUTIONS OF UREA AT THE CONCENTRATIONS INDICATED

Molar concentration	0	0·02	0·04	0·08	6·0
Percentage hatch	6·7	5·3	8·3	31·7	0
Percentage mortality	5·3	0	4·0	32·0	100

(2) The capacity of urea to increase the rate of termination of diapause was revealed in the following experiment. Pre-diapause eggs were treated with urea at a concentration, 0·02 *M*, insufficient to eliminate diapause in eggs held at 27° C. When held at this temperature, 95 per cent of the eggs, both treated and controls, entered diapause.

Incubation was continued at 27° C. until the completion of hatching. The median duration of exposure (period for 50 per cent hatch) was 35 days for the eggs treated with urea, in comparison with 54 days for the control.

Evidence to be described elsewhere shows urea to be absorbed into the egg.

The low concentration of urea in the above experiments would seem to make it unlikely that denaturation takes place. Nevertheless, relatively mild agents can cause reactions of this type, such as sulphydryl – disulphide exchange[4], or disturbance of the protein hydration structure (ref. 5 and personal communication). Although no reactions to concentrations as low as those reported here have been described, the possibility of steric effects must be considered.

A more detailed report of these and other experiments will be published elsewhere.

The Prothoracic Gland and Colour Change in Locusts

MANY locust species are characterized by large variations in colour, morphometrics and behaviour, variations which are related, under natural conditions, to the density of the population[1]. When numbers are high the nymphs, or hoppers, live in dense bands, and these gregarious hoppers are orange or yellow and black in colour. When populations are low the hoppers do not group together, and such solitary locusts are fawn or green, with only small amounts of darker pattern. In the laboratory, gregarious locusts may be produced by rearing the hoppers in crowds, and solitary locusts by rearing each individual in a separate cage, out of visual and tactile contact with others[2]. The behaviour of locusts changes rapidly, according to the number of contacts that hoppers make with each other[3]. Changes in colour and in morphometrics require more continuous contact (or lack of contact) with other locusts[4,5]. It has been suggested that the colour changes are controlled, at least in part, by hormones, and that the hormonal balance of solitaries differs from that of gregarious individuals[5,6].

During an endocrinological investigation of two species of locusts, *Locusta migratoria migratorioides* (R. and F.) and *Schistocerca gregaria* (Forsk.), we observed that the prothoracic gland (ventral gland) is shaped differently and significantly larger in solitary than in gregarious individuals (Fig. 1). The corpus allatum was also slightly larger in solitary individuals, while there was no apparent difference in the size of the corpus cardiacum. The larger size of the prothoracic gland in solitary individuals suggested the experiment of extirpating part of this glandular tissue, leaving *in situ* an amount approximately equal to that found in gregarious animals. The results of preliminary experiments of this kind, performed on nine pairs of *Schistocerca* hoppers, have substantiated the validity of this approach to the problem of colour change in locust phases. The hoppers were reared in isolation from hatching and throughout the course of the experiment. Soon after the moult to the fourth instar, hoppers were matched in pairs of the same sex and coloration. In one of each pair, three-quarters of the prothoracic gland on one side was then removed. The other animal of the pair was subjected to a blank operation and served as a control. Before the operation the animals were green in colour, with varying small amounts of blackish-brown pattern. After the moult, to the fifth instar, the hoppers that had been deprived of a portion of the prothoracic gland had developed extensive areas of black pigmentation, similar to that of gregarious hoppers, while the background colour had changed from green to yellow or creamy-pink, similar to that found in gregarious hoppers, or in those which are becoming gregarious[4]. The

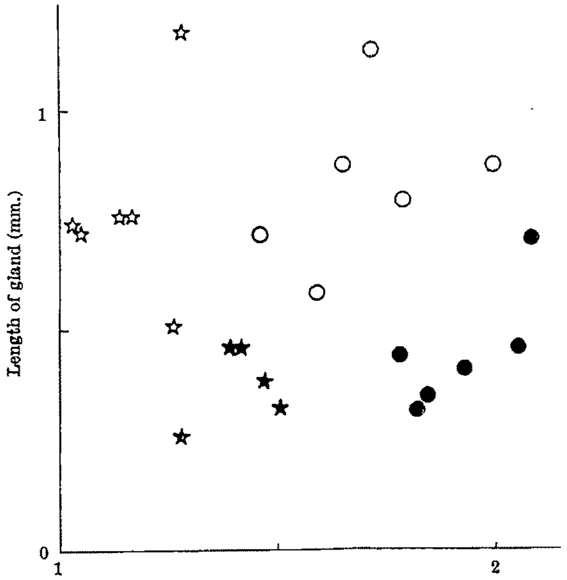

Fig. 1. The size (greatest antero-posterior measurement) of the prothoracic gland in solitary and gregarious adults of *Schistocerca gregaria* killed within 6 hr. of fledging. Open symbols, solitary animals ; solid black symbols, gregarious animals ; stars, males ; circles, females

control hoppers remained green in colour with only small amounts of black pattern.

These results seem to provide evidence that secretions of the prothoracic gland play a part in governing the metabolism of the pigments and, in balance with other hormones, in controlling changes in colour from the solitary to the gregarious phase in locusts. Further work is in progress relating to the possible role of hormone balance in other aspects of locust biology, especially behaviour.

Experimental Hybridization of *Aedes* (*Stegomyia*) *aegypti* (L.) with *A.* (*S.*) *simpsoni* (Theobald)

Hybridization between *Aedes* (*Stegomyia*) *aegypti* (L.) and the morphologically very distinct[1] *A.* (*S.*) *albopictus* Skuse has been a source of keen controversy since the initial work of Toumanoff[2] and Hoang Tich Try[3]. These results and those of Downs and Baker[4] and Bonnet[5] have been fully discussed by Kitzmiller[6] and Mattingly[1]. Offspring were only obtained in one direction in each case, though the successful direction varied with the strains used. Inheritance was completely maternal in the F_1 and subsequent generations with the exception of two single individuals of paternal resemblance. Suggested explanations involve sperm-entry induced parthenogenesis[4], cytoplasmic inheritance[7] and chromosomal mechanisms[1]. Recently, Woodhill[8] has repeated the crosses on a much larger scale with stringent precautions to avoid contamination. From nearly 50,000 eggs only a single adult was obtained, intermediate in characters between the two parents, indicating a certain degree of chromosomal compatibility.

A. (*S.*) *simpsoni* (Theobald) is morphologically much closer to *A. aegypti* than is *A. albopictus*, widespread in the Ethiopian region, frequently occurring together with *A. aegypti* and an important vector of yellow fever; it is nevertheless of distinct habits, breeding almost exclusively in plant axils while *A. aegypti* does so only rarely. *A. simpsoni* used in the present work were the F_1 from wild-laid eggs collected at Ganda, Kenya, by members of the Medical Department, to whom I am indebted. The adults reared in London were hand-mated[9] (normal mating does not occur under usual laboratory conditions); 8 out of 10 mated females oviposited normally and 7 of the egg batches were fully fertile. The *A. aegypti* used were a heterogeneous F_2 from larvæ collected at Port Swettenham, Malaya, through the kindness of Dr. R. H. Wharton of Kuala Lumpur. Mostly var. *queenslandensis*[10], they were largely heterozygous for the genes for white abdomen[11] and white-spot[12] and mated naturally in ½-pint paper cups.

In making the crosses the females were first given a blood meal and then hand-mated[9] with males of the other species. The mated females were confined in a 3 × 1 in. tube over a moist pad on which they oviposited. Hatching was effected by adding deoxygenated water to these tubes.

18 out of 19 female *A. simpsoni* mated with male *A. aegypti* laid egg batches, from 4 of which 9 larvæ hatched. 7 out of 17 female *A. aegypti* of the reciprocal mating laid egg batches, none of which hatched. 3 of the larvæ died before reaching the 4th instar; the remainder, from 3 different matings, were reared to give 2 identical adult males and 4 identical adult females in perfect condition. A male and female are illustrated in Fig. 1 together with examples of the parental species.

These hybrids have some characters typical of one parent and some of the other, with a few intermediate between the two. Characters typical of the maternal parent *A. simpsoni* include the spines at the base of the thoracic tufts of the 4th-stage larvæ, absence of any scales on the clypeus, the anterior scutal spot large and broad-scaled and the supra-alar spot large.

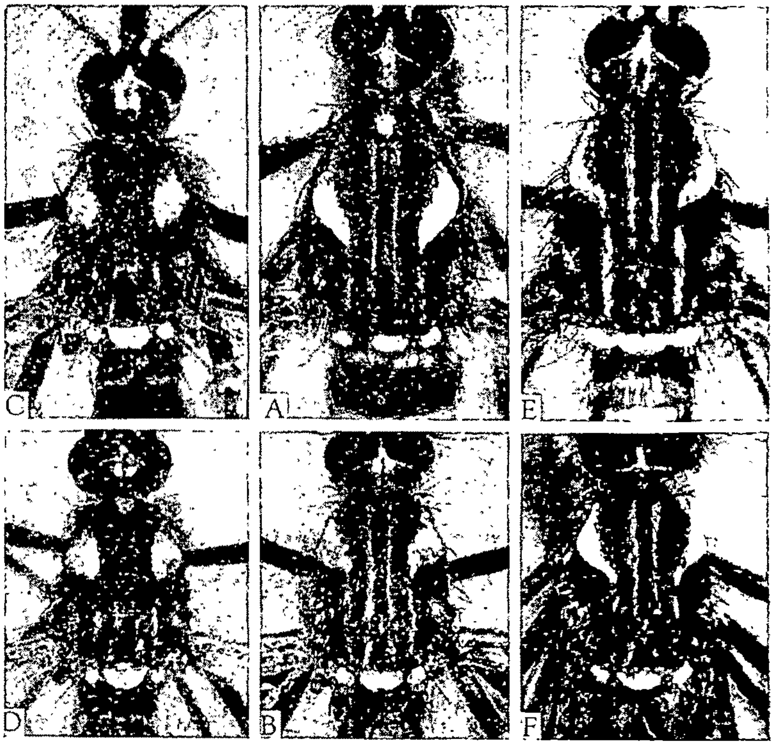

Fig. 1. A hybrid between the mosquitoes *Aedes* (*Stegomyia*) *aegypti* (L.) and *A.* (*S.*) *simpsoni* (Theobald). The thoraces of *A*, ♀ hybrid; *B*, ♂ hybrid; *C*, ♀ and *D*, ♂ maternal species *A. simpsoni*; *E*, ♀ and *F*, ♂ paternal species *A. aegypti*

Characters typical of *A. aegypti* include the median paired yellow lines on the scutum, the front femora with anterior pale stripes on the basal halves and the mid femora with anterior pale stripes and no median spots. Intermediate characters include the larval pecten-spines which have large basal denticles as in *A. aegypti* but are bilaterally symmetrical; the anterolateral scutal spots are a compromise between ovoid in *A. simpsoni* and crescentic in *A. aegypti* (Fig. 1), the 4th hind tarsal, pale on the basal two-thirds in *A. aegypti* and entirely dark in *A. simpsoni*, is pale on the basal one-third.

These hybrids represent about 1 per cent of the eggs laid in the particular cross, compared with not more than about 0·06 per cent in the case of Woodhill's hybrid[8]. This seems reasonable in view of the closer affinity between the species in the present instance, although it is possible that hand-mating may result in better insemination than natural mating. The uniformity among the 4 female and 2 male hybrids suggests that chromosomal combination, though rare, is constant in its effect. The absence of offspring in the reciprocal cross must remain inconclusive until more successful matings have been made. The results support Woodhill's[8] suggestion that the earlier results with *A. albopictus* might be due to contamination by stray eggs. True hybridization when it occurs between *Stegomyia* species probably results in a blending inheritance with a frequency of occurrence indicative of the extent of evolutionary divergence within the subgenus.

VIROLOGY

Use of a 'Mixed Hæmadsorption' Method in Virus-infected Tissue Cultures

THE principle of mixed agglutination[1] has been used by Högman[2] to indicate the presence of blood-group antigens in tissue culture. In this system the cultured cells are sensitized with antibodies directed towards antigens of the cell surface. Thereby the cells acquire capacity to adsorb homologous red cells. Vogel and Shelokov[3] have shown that certain viruses can be located in tissue cultures by their capacity to adsorb sensitive erythrocytes, the so-called hæmadsorption test. Two pre-requisites for this system are: (1) that virus antigen be available on the surface of the infected tissue cells; (2) that this antigen fix the erythrocytes.

This communication outlines some attempts to apply a similar system to indicate virus antigens present on tissue culture cell surfaces, but which do not fix red cells spontaneously. Initially cells infected with vaccinia virus were chosen as an experimental model because viral antigen located on the cell surface is assumed to exist (spontaneous hæmadsorption with chicken erythrocytes). The sheep red cells used in the present experiments are not spontaneously adsorbed on vaccinia-infected cells unless treated as described here.

Table 1. 'MIXED HÆMADSORPTION' IN VACCINIA VIRUS-INFECTED TISSUE CULTURES TREATED WITH DIFFERENT CONCENTRATIONS OF ANTI-VACCINIA RAT SERUM.

Positive hæmadsorption graded as + + +, + + or +; – indicates no hæmadsorption

	Indicator cells	Dilution of rat serum added to the tubes					
		Anti-vaccinia serum					Normal rat serum
		10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-2}
Vaccinia virus-infected tubes	Positive cells	+ + +	+ +	+	(+)	–	–
	Negative cells	–					
Normal tube	Positive cells	–					

Positive cells, tanned sheep erythrocytes coated with 100 γ/ml. rat globulin and rabbit anti-rat serum 1/1,000. Negative cells, as above except anti-rat serum substituted for normal rabbit serum diluted /1,000.

Viral antibodies obtained from either rats or rabbits were fixed to virus-infected tissue culture cells and detected by the addition of sheep red cells coated with antiserum to either rat or rabbit sera, depending on the source of the viral antibodies.

The vaccinia virus was grown in monolayer cultures of monkey kidney tissue. Tubes with moderate virus degeneration were washed three times with the culture medium used (usually 0·5 per cent lactalbumin hydrolysate buffered with Hanks solution) and drained. Then 0·2 ml. of rabbit or rat antivaccinia serum was added in different dilutions to the virus cultures (Table 1). The tubes were kept at room temperature for 1 hr. in a slightly inclined position (about 10°) and were then carefully washed three times. Following this, the indicating system, sheep red cells coated with the specific anti-γ-globulin serum on their surface, were added to the tubes. It was established that if antibodies were fixed to the tissue culture, then, the red cells would agglutinate around the tissue cells as shown in Fig. 1.

The specific species antiserum, prepared in horse (anti-rabbit serum) or rabbit (anti-rat serum), can be fixed to the sheep red cells in two ways. One method consists of coating tanned sheep cells[4] with, for example, rat γ-globulin 50–100 γ/ml. Rabbit anti-rat serum was then allowed to combine with the coated sheep cells in a dilution of the serum (1/1,000) that produced agglutinates of moderate size.

The other method differs only in that the sheep cells were not tanned, but were sensitized with rabbit immune (anti-sheep) serum, and then allowed to combine with anti-rabbit sera, of which a suitable dilution was also chosen.

The result of a representative experiment with vaccinia virus-infected cultures is shown in Table 1. It can be seen that anti-viral serum when added to vaccinia-infected cultures in dilutions up to 1/10,000 will absorb 'positive' red cells. (The HI-titre of this serum measured in the conventional way against

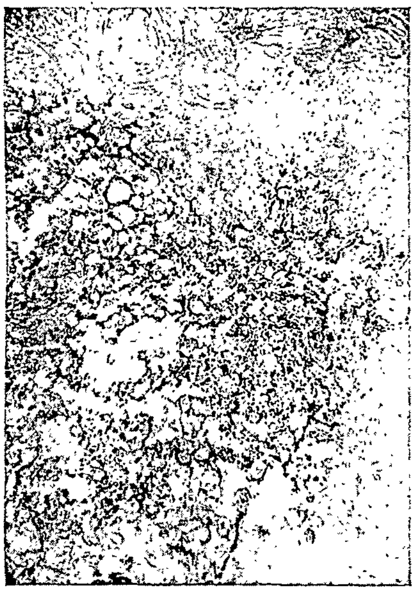

Fig. 1. Photomicrograph showing positive 'mixed hæmadsorption' on a vaccinia virus degeneration focus. Tissue culture from the experiment summarized in Table 1

4 units of vaccinia hæmagglutinin was 1/512, and the 50 per cent plaque neutralizing titre was about 1/3,000). The specificity of the system is indicated by the negative outcome of the controls given in Table 1.

Experiments have shown that essentially the same results are obtained in the vaccinia virus system when the indicating cells are prepared according to the second method, that is, sheep erythrocytes covered with, for example, rabbit anti-sheep serum and followed by anti-rabbit serum.

This latter system has also been tried with success in tissue cultures infected with measles or canine distemper virus as shown in Table 2.

The hæmadsorption on virus-infected foci was massive, and clearly visible macroscopically. When viewed microscopically, it was found that the red cells clump on the edges of the infected cells. In addition, when a very strong hæmadsorption occurred, the red cells covered the entire cell surface, presumably because the binding was strong enough to prevent the red cells from being washed away.

Attempts have been made to use this method of detection for other virus – tissue culture systems, such as those of polio and herpes simplex, but the results have been negative to date. This may be due to a difference in the release of the viruses from the infected cells as compared with that of the vaccinia and distemper viruses.

Table 2.* 'MIXED HÆMADSORPTION' IN TISSUE CULTURES INFECTED WITH CANINE DISTEMPER VIRUS. HÆMADSORPTION GRADED AS IN TABLE 1

	Indicator cells	Rabbit serum added to tubes: Anti-distemper serum dilution 1/5	
		Anti-distemper serum dilution 1/5	Normal serum dilution 1/5
Distemper virus infected tubes	Positive cells	+ + +	–
	Negative cells	–	–
Normal tubes	Positive cells	–	–
	Negative cells	–	–

Positive cells, washed sheep red cells coated with rabbit amboceptor (anti-sheep erythrocyte serum produced in rabbit) diluted 1/1,000 and with horse anti-rabbit serum diluted 1/500. Negative cells, as above, but anti-rabbit serum substituted for normal horse serum 1/500.

* This experiment was performed in co-operation with Dr. Erling Norrby.

New Herbaceous Test-Plants for Study of the Infectious Degeneration of Grape Vines

RECENT progress achieved in the transmission of the virus diseases of the grape vine to herbaceous test-plants, induces us to disclose further results[1].

In a series of inoculations made on 1,026 plants, of 48 different species, using various techniques, positive results were obtained in the following tests: (1) by mechanical inoculation of sap, (*a*) on *Impatiens holstani* (*I. holstii* × *I. sultani*) (one plant out of 48 of which 17 were in artificial light and 31 in greenhouse; experiments made during various periods of the year) with leaves of the clone of grape vine Alfa *T.A.*, (*b*) on alfalfa (two plants out of six) with roots of the clone 34*C*/59; (2) by chip-budding from young shoots, (*a*) on *I. holstani* (one plant out of 18) with the clone 101*P*, (*b*) on *Lycopersicum esculentum* (4 plants out of 30) with the clone 16*C*/59, (*c*) on the hybrid *L. esculentum* × *L. pimpinellifolium* (7 plants out of 13), with the clone 1*C*/59; (3) by dodder, on *Ammi majus* (10 plants out of 19) in five experiments made from February to June, with the clones of grape vine 3*CA*/59, *V*1*F*22*V*1, and 101*P*.

For the transmission, material was used from 32 different clones of diseased grape vines. Results were positive with only seven of them, coming from three different districts and showing at the same time malformation of the shoots and of the leaves, mosaic and yellow mosaic. These are the only symptoms noticed so far in Italy on the 'infectious degeneration' of the grape vine.

The following are the symptoms observed on the herbaceous test plants: *I. holstani*—severe malformation and twisting of the leaves, accompanied by mosaic and yellow streaks (after 4 months, by sap inoculation and after 3 months, by chip-budding); Alfalfa—mild mosaic or yellowish spots with sharp or indefinite edges on the leaves (after about 30 days); *L. esculentum* and *L. esculentum* × *L. pimpinellifolium*—vein-clearing and leaf malformation (after 30–50 days); *A. majus*—malformation and twisting of the leaves with light green or necrotic patterns along the margin (after 10–30 days).

We deduced that viruses were transmitted from the vine to herbaceous plants since: (*a*) with *I. holstani*, although the percentage of infections is very slow, we had the same symptoms using two different methods of transmission and working during different periods of the year; (*b*) with *A. majus* the percentage of infection is quite high, and, moreover, we had the transmission, only by dodder, on the same species (after 17 days); (*c*) the same clone of grape vine gave positive results on *A. majus* and *I. holstani*; (*d*) transmission made in different periods of the year gave the same symptoms; (*e*) on *L. esculentum* × *L. pimpinellifolium* the symptoms were identical both in the inoculation from the vine and from diseased *I. holstani*.

From *I. holstani* the isolate has so far been transmitted to tobacco (varieties White Burley and Samsun) and to *Petunia*, by sap and by *Myzodes persicae*; to *Nicotiana glutinosa, Datura stramonium, Vigna sinensis* and *I. holstani* by sap. The percentage infection in the transmission from these species to the same species or to the other species that gave positive results in the inoculation from *I. holstani*, is higher than in the transmission from *I. holstani*.

We are trying to transmit the isolates from the herbaceous plants to grape vine. For this work we use symptomless grape vines, selected during three years and belonging to varieties that appeared to be very receptive to the 'infectious degeneration' in previous experiments on transmission by grafting from vine to vine.

Other work in progress is the identification of the isolates.

No rod-shaped virus particles were seen in a series of observations, using the electron microscope, with exudates obtained by Johnson's method and with drops prepared with Brandes's dipping method both with diseased grape vines (leaves, shoots and roots) and with infected herbaceous plants.

GENETICS

Gene Action in the X-chromosome of the Mouse (*Mus musculus* L.)

Ohno and Hauschka[1] showed that in female mice one chromosome of mammary carcinoma cells and of normal diploid cells of the ovary, mammary gland and liver was heteropyknotic. They interpreted this chromosome as an X-chromosome and suggested that the so-called sex chromatin was composed of one heteropyknotic X-chromosome. They left open the question whether the heteropyknosis was shown by the paternal X-chromosome only, or the chromosome from either parent indifferently.

The present communication suggests that the evidence of mouse genetics indicates: (1) that the heteropyknotic X-chromosome can be either paternal or maternal in origin, in different cells of the same animal; (2) that it is genetically inactivated.

The evidence has two main parts. First, the normal phenotype of XO females in the mouse[2] shows that only one active X-chromosome is necessary for normal development, including sexual development. The second piece of evidence concerns the mosaic phenotype of female mice heterozygous for some sex-linked mutants. All sex-linked mutants so far known affecting coat colour cause a 'mottled' or 'dappled' phenotype, with patches of normal and mutant colour, in females heterozygous for them. At least six mutations to genes of this type have been reported, under the names mottled[3,4], brindled[3], tortoiseshell[5], dappled[6], and $26K$ [2]. They have been thought to be allelic with one another, but since no fertile males can be obtained from any except, in rare cases, brindled, direct tests of allelism have usually not been possible. In addition, a similar phenotype, described as 'variegated', is seen in females heterozygous for coat colour mutants translocated on to the X-chromosome[7,8].

It is here suggested that this mosaic phenotype is due to the inactivation of one or other X-chromosome early in embryonic development. If this is true, pigment cells descended from cells in which the chromosome carrying the mutant gene was inactivated will give rise to a normal-coloured patch and those in which the chromosome carrying the normal gene was inactivated will give rise to a mutant-coloured patch. There may be patches of intermediate colour due to cell-mingling in development. The stripes of the coat of female mice heterozygous for the gene tabby, *Ta*, which affects hair structure, would have a similar type of origin. Falconer[9] reported that the black regions of the coat of heterozygotes had a hair structure resembling that of the *Ta* hemizygotes and homozygotes, while the agouti regions had a normal structure.

Thus this hypothesis predicts that for all sex-linked genes of the mouse in which the phenotype is due to localized gene action the heterozygote will have a mosaic appearance, and that there will be a similar effect when autosomal genes are translocated to the X-chromosome. When the phenotype is not due to localized gene action various types of result are possible. Unless the gene action is restricted to the descendants of a very small number of cells at the time of inactivation, these original cells will, except in very rare instances, include both types. Therefore, the phenotype may be intermediate between the normal and hemizygote types, or the presence of any normal cells may be enough to ensure a normal phenotype, or the observed expression may vary as the proportion of normal and mutant cells varies, leading to incomplete penetrance in heterozygotes. The gene bent-tail, *Bn* [10], may fit into this category, having 95 per cent penetrance and variable expression in heterozygotes. Jimpy, *jp*, is recessive, suggesting that the presence of some normal cells is enough to ensure a normal phenotype, but Phillips[11] reported one anomalous female which showed the jimpy phenotype. Since it showed the heterozygous phenotype for *Ta* this animal cannot be interpreted as an XO female; it is possible that it represents an example of the rare instance when by chance all the cells responsible for the jimpy phenotype had the normal gene inactivated.

The genetic evidence does not indicate at what stage of embryonic development the inactivation of one X-chromosome occurs. In embryos of the cat, monkey and man sex-chromatin is first found in nuclei of the late blastocyst stage[12,13]. Inactivation of one X at a similar stage of the mouse embryo would be compatible with the observations. Since an XO female is normally fertile it is not necessary to postulate that both X-chromosomes remain functional until the formation of the gonads.

The sex-chromatin is thought to be formed from one X-chromosome also in the rat, *Rattus norvegicus*[14], and in the opossum, *Didelphis virginiana*[15]. If this should prove to be the case in all mammals, then all female mammals heterozygous for sex-linked mutant genes would be expected to show the same phenomena as those in the mouse. The coat of the tortoiseshell cat, being a mosaic of the black and yellow colours of the two homozygous types, fulfils this expectation.

Genetic Basis for Graft-against-Host Immunological Reactions between Two Inbred Lines of Chickens

IT has been established that the enlargement of the embryonic spleen which follows the injection of adult chicken blood into chick embryos is due, at least in part, to a proliferation of cells derived from the injected blood[1,2]. Cock and Simonsen[3] have shown that virtually no splenic enlargement occurs when the blood-donor and embryonic recipients are members of the same inbred line of chickens. The phenomenon of splenic enlargement seems to be fundamentally immunological in nature, and due to donor cells proliferating in response to those host antigens which differ from any in the donor.

It should be possible, by injecting blood from adult birds from one parental line into F_2-generation and back-cross embryos between two inbred lines, to analyse the antigenic difference of the other parental line. Assuming that the antigens of the parental lines are dominantly determined and that they segregate in crosses between the lines in a Mendelian fashion, then a proportion of F_2-generation embryos, and of embryos of the back-cross to the parent of the blood-donating line, will be expected to lack those genes which determine antigens occurring exclusively in the non-blood-donating line. The proportion of embryos which lack these genes will be $(\frac{1}{4})^n$ in the F_2-generation and $(\frac{1}{2})^n$ in the back-cross, where n is the number of pairs of genes involved. Since splenomegaly will occur only when the recipient embryo possesses antigens foreign to the donor cells, these are also the proportions of embryos in the respective crosses which will show no splenic enlargement. All F_1 hybrids and embryos of the back-cross to the parent of the non-blood-donating line will receive the genes which determine antigens peculiar to the non-blood-donating line and all these embryos will therefore show splenic enlargement. Thus, an estimate of the value of n can be obtained by observing the proportion of F_2 and back-cross embryos which show no splenic enlargement. The genetic basis for this method is essentially similar to that used in analysing histo-compatibility differences between inbred strains of mice using tumour transplantation[4], and skin transplantation[5].

The method outlined above has been used to observe antigenic differences between the Reaseheath C- and I-inbred lines of White Leghorns[6]. Both lines have been brother-sister mated annually for more than twenty generations. Chick embryos were injected intravenously at 15 days of incubation with 0·1 ml. of citrated blood from I-line cocks, and killed 4 days later and their spleens weighed. The embryos injected were: C-line embryos, I-line embryos, the F_2-generation ($CI \times CI$ and $CI \times IC$), and the back-crosses ($C \times CI$ and $C \times IC$, $I \times CI$ and $I \times IC$). In designating the crosses, the male parent is stated first. Two I-line cocks were used as blood-donors to the F_2 and back-cross embryos and experiments with each donor were performed twice. Only a small number of C embryos were available for injection, but the marked splenic enlargements obtained indicate that C tissues are antigenic to I cells. A small number of I-line embryos injected with I-blood showed no splenomegaly. So far, we have had no F_1-hybrids to test, but Cock and Simonsen[3] have obtained splenic enlargement after injecting I-blood into newly hatched $C \times I$ chicks. The patterns of spleen weights obtained after injecting I-blood into F_2 and back-cross embryos were similar in each of the four experiments, and the results have been pooled in Fig. 1. The proportions of spleens in the different crosses showing no enlargement are shown in Table 1, and these results are compared with the theoretical frequencies expected for 1, 2 and 3 pairs of dominant genes determining antigens peculiar to the C-line. The proportions best fit the expectancy for one pair of genes, and the results suggest, therefore, that the C-line carries one antigen (capable of stimulating splenic enlargement) which is absent from the I-line. The results also fit the expectancy if the C-line possesses one dominantly determined antigen and one recessively determined antigen foreign to the I-cells. In this case, the proportion of unenlarged spleens in the F_2-generation would be 18·75 per cent (the proportion falls in a series $(\frac{3}{4})^{n_1} \times (\frac{1}{4})^n$, where n_1 is the number of pairs of recessive genes and n is the number of pairs of dominant genes). The proportion of unenlarged spleens in the back-crosses would remain unchanged. However, until we have other evidence for the

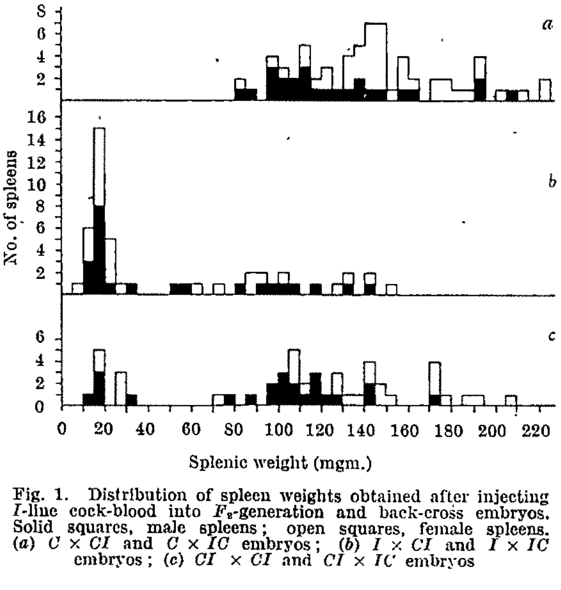

Fig. 1. Distribution of spleen weights obtained after injecting I-line cock-blood into F_2-generation and back-cross embryos. Solid squares, male spleens; open squares, female spleens. (*a*) $C \times CI$ and $C \times IC$ embryos; (*b*) $I \times CI$ and $I \times IC$ embryos; (*c*) $CI \times CI$ and $CI \times IC$ embryos

Table 1

Pairs of genes	Percentage of unenlarged spleens in F_1	Percentage of unenlarged spleens in F_2	Percentage of unenlarged spleens in back-crosses	
	CI	*CI* × *CI* *CI* × *IC*	*I* × *CI* *I* × *IC*	*C* × *CI* *C* × *IC*
Experimental results	no data	20·4 } $\chi^2 = 0·55$	59·2 } $\chi^2 = 1·65$	0
1	0	25 } N.S.	50 } N.S.	0
2	0	6·25	25	0
3	0	1·56	12·5	0

Comparison between experimental segregation results and theoretical results expected for 1, 2 and 3 pairs of genes determining antigens present in *C*-line birds, but absent from *I*-line birds. The experimental data do not differ significantly from the values expected for one pair of genes.

Table 2. DIFFERENCES IN MEAN WEIGHTS OF ENLARGED SPLEENS FROM MALE AND FEMALE EMBRYOS

Cross	No. of embryos	Mean splenic weight (mgm.)		Values of *t* (from logarithm of spleen weights)
		Male	Female	
C × *CI* and *C* × *IC*	68	128·3	151·6	2·97 $P < 0·01$
I × *CI* and *I* × *IC*	20	98·2	105·7	0·55 $P > 0·5$
CI × *CI* and *CI* × *IC*	39	114·1	145·5	3·33 $P < 0·01$

occurrence of recessively determined antigens in the chicken, we are inclined to favour the former interpretation of the segregation results.

The spleens of uninjected control embryos ranged in weight from about 10 to 20 mgm. The slight enlargements (up to 35 mgm.) of some spleens which have been included in the 'no enlargement' groups in Table 1 may be attributable to the presence of additional weak antigens in the *C*-line. On the other hand, the slight antigenic diversity which exists within the *I*-line[3] must also contribute to these small enlargements.

The different patterns of distribution of the enlarged spleens in the three crosses suggest that the homozygotic or heterozygotic state of the gene determining the *C* antigen influences the spleen weight. That is, a gene dosage effect appears to be involved, with embryos homozygous for the *C* gene providing a stronger antigenic stimulus to *I* cells (and therefore a larger spleen) than embryos heterozygous for the gene. However, the weight of the spleen may probably not be taken as directly indicative of the homozygosity or heterozygosity of the embryo concerned, since there is evidence in two of the crosses that the sex of the recipient influences the spleen weight. The mean weights of the enlarged female spleens from *C* × *CI* and *C* × *IC* and from *CI* × *CI* and *CI* × *IC* embryos are significantly greater than the mean weights of enlarged male spleens (Fig. 1 and Table 2). The reason for this sex difference is not known; a similar effect has been observed by J. B. Solomon (personal communication). In addition to the sex and gene dosage effects, the variability in weight of the enlarged spleens will also be increased by residual antigenic diversity within both the *C*- and *I*-lines.

These results will be reported in more detail elsewhere, together with results obtained by injecting *C*-line blood into the *C*- and *I*-crosses. Similar analyses of differences between the *C*- and *W*-inbred lines will also be described.

We wish to thank Dr. P. A. Gorer, who kindly commented on the manuscript. Our thanks are also due to Miss R. Ford for technical assistance and to the Agricultural Research Council for a grant which supported this work.

MISCELLANY

Extra-Terrestrial Radio Transmissions

WE are witness again to a surge of interest in, and speculation about, extra-terrestrial radio transmissions which had an earlier flare in the late 'twenties[1]. The favourable change in climate for the expression of such ideas since the turn of the century has been of particular interest to me. In 1899, Nikola Tesla established an experimental station at Colorado Springs, where he would be free to pursue certain electrical investigations, unrestrained by the limits imposed by his New York City laboratory. In an article by him[2], published after his return to New York in the following year, he presented a rather thrilling account of signals received while alone one night in the experimental station:

"The changes I noted were taking place periodically, and with such a clear suggestion of number and order that they were not traceable to any cause then known to me. I was familiar, of course, with such electrical disturbances as are produced by the sun, Aurora Borealis and earth currents, and I was as sure as I could be of any fact that these variations were due to none of these causes. . . . It was some time afterward when the thought flashed upon my mind that the disturbances I had observed might be due to intelligent control. . . . The feeling is constantly growing on me that I had been the first to hear the greeting of one planet to another. . . . I announced to the Red Cross Society, when it asked me to indicate one of the great possible achievements of the next hundred years, that it would probably be the confirmation and interpretation of this planetary challenge to us."

I have acquired the original of Tesla's statement to the Red Cross Society, dated Christmas (January 7), 1900, which I believe is the first expression of the possibility of radio communication with other planetary communities. The announcement was harshly criticized. This was particularly unfortunate, since, because of such attacks, Tesla never produced detailed information concerning the results of his intended investigations and the chance reception of signals.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, April 24

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. J. A. Steers and others : "Coastal Cliffs".

BRITISH NUCLEAR ENERGY CONFERENCE (at the Federation of British Industries, 21 Tothill Street, London, S.W.1), at 5.30 p.m.—Mr. A. M. Weinberg (Oak Ridge National Laboratory): "The Development of Fluid Fuel Reactors".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. G. W. Green: "Development of City Distribution Systems".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. G. Gee, F.R.S.: "Polymer Science in the University" (Jubilee Memorial Lecture).

Tuesday, April 25

INSTITUTION OF AGRICULTURAL ENGINEERS (at the Piccadilly Hotel, London, W.1), at 10.30 a.m.—Annual General Meeting. 11.15 a.m.—Conference. 7 p.m.—Dinner.

BRITISH BIOPHYSICAL SOCIETY (in the Physics Department, Birkbeck College, Malet Street, London, W.C.1), at 11 a.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS, MEASUREMENT AND CONTROL SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. D. M. Mackay : "Simulation of Intelligence".

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. A. S. Lodge: "The Rheology of Concentrated Polymer Solutions".

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. A. H. Pople: "Instrumentation in the Iron and Steel Industry".

Wednesday, April 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Sir John Cockcroft, O.M., F.R.S.: "The Training of Scientists for Industry" (Trueman Wood Lecture).

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Annual General Meeting. Prof. S. E. Hollingworth: "The Climatic Factor in the Geological Record" (Presidential Address).

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS AND COMMUNICATIONS SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. H. Franklin and Mr. J. Rhodes: "Data Transmission".

CHALLENGER SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—Annual General Meeting. Mr. R. L. Coet: "The Movement of Brake Bank, South of Ramsgate".

BRITISH INSTITUTION OF RADIO ENGINEERS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Symposium on "Electronic Counting Techniques".

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Annual Report of the Council.

Wednesday, April 26—Friday, April 28

BRITISH INSTITUTE OF RADIOLOGY (at the Central Hall, Westminster, London, S.W.1)—Twenty-second Annual Congress. Exhibition of Equipment and Materials used in Medical Radiology and Radiotherapy.

Thursday, April 27

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Meeting for the election of Foreign Members, followed by Mr. D. Lowe: "The National Vegetable Research Station".

ROYAL SOCIETY OF ARTS, COMMONWEALTH SECTION (joint meeting with the ROYAL COMMONWEALTH SOCIETY, at John Adam Street, Adelphi, London, W.C.2), at 5.15 p.m.—The Right Hon. The Earl De La Warr, P.C., G.B.E.: "The Work of the Commonwealth Societies".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Prof. F. Lynen (Munich): "Biological Pathways to the Carbon Skeleton in Natural Products".* (Further lectures on May 1 and 2.)

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. R. F. Woolmer: "Medical Electronics" (Fifty-second Kelvin Lecture).

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Mr. H. J. Bunker: "Recent Microbiological Problems in Industry".

Friday, April 28

BRITISH PSYCHOLOGICAL SOCIETY, OCCUPATIONAL PSYCHOLOGY SECTION (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Miss Lisle Klein: "Some Implications of Rationalized Production".

WORSHIPFUL SOCIETY OF APOTHECARIES OF LONDON, FACULTY OF THE HISTORY OF MEDICINE AND PHARMACY (at the Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, London, E.C.4) at 4.30 p.m.—Second Annual General Meeting. 5 p.m.—Sir Geoffrey Keynes: "Timothy Bright" (Gideon de Laune Lecture).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. Edwin H. Land (U.S.A.): "Colour in the Natural Image".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

LECTURER or ASSISTANT LECTURER IN AGRICULTURAL BOTANY—The Registrar, The University, Leeds 2 (April 28).

ASSISTANT LECTURER, Grade B, IN PHYSICS, to teach in the first instance up to General Certificate of Education "A" level, and Part 1 B.Sc. General Degree—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (April 29).

LECTURER (with a special interest in crop husbandry) IN THE DEPARTMENT OF AGRICULTURE—The Secretary, The University, Edinburgh (April 29).

LECTURER or ASSISTANT LECTURER IN BACTERIOLOGY—The Registrar, The University, Leeds 2 (May 1).

LECTURER (preferably, though not necessarily, with some industrial experience and interested in teaching and research in one or more of the following fields: electrical machines; electrical power; computers, or electronics) IN ELECTRICAL ENGINEERING—The Registrar, The University, Nottingham (May 5).

READER IN APPLIED MATHEMATICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (May 5).

ASSISTANT LECTURER (preferably with an interest in mycology) IN BOTANY—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (May 8).

ASSISTANT LECTURER or LECTURER IN THE DEPARTMENT OF ZOOLOGY—The Registrar, The University, Liverpool 3 (May 10).

LECTURER (with a special interest in mycology, plant pathology or cognate subjects) IN BOTANY—The Secretary, The Queen's University of Belfast, Belfast 7, Northern Ireland (May 10).

PROFESSOR OF ORGANIC CHEMISTRY—The Secretary and Bursar, University College, Dublin (May 15).

ASSISTANT LECTURER IN THE DEPARTMENT OF APPLIED MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (May 20).

CHAIR OF ZOOLOGY—The Registrar, University College of Wales, Aberystwyth (May 20).

FRUIT RESEARCH OFFICER (PHYSIOLOGIST) (honours graduate in science or agricultural science, or equivalent qualifications, with relevant postgraduate research experience, preferably in plant physiology or biochemistry) at the new Headquarters Laboratories of the Division of Food Preservation, C.S.I.R.O., North Ryde, Sydney, Australia, to participate in a programme of physiological and biochemical investigations to obtain a better understanding of the ripening of fruit and its behaviour in storage—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 300/298 (May 20).

LECTURER IN ZOOLOGY at Fourah Bay College (University College of Sierra Leone), to specialize in marine work—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 20).

SENIOR FELLOW and a SENIOR RESEARCH FELLOW (preferably with experience in elementary particle physics) IN THE DEPARTMENT OF THEORETICAL PHYSICS, Institute of Advanced Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, May 26).

LECTURER IN BIOCHEMISTRY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, May 31).

SENIOR LECTURER IN PSYCHOLOGY; and a SENIOR DEMONSTRATOR IN PSYCHOLOGY, in the Department of Psychology, School of General Studies, Australian National University, Canberra, A.C.T., Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, June 24).

ASSISTANT PROFESSOR (with a Ph.D. or equivalent, and subsequent academic, industrial or research experience) OF METALLURGY—Prof. F. A. Forward, Department of Metallurgy, University of British Columbia, Vancouver, B.C., Canada (June 30).

SENIOR LECTURER (preferably with a degree in pharmacology, physiology or biochemistry) in PHARMACOLOGY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, June 30).

MIDDLEMASS HUNT CHAIR OF TROPICAL HYGIENE—The Registrar, The University, Liverpool (July 1).

ASSISTANT PROFESSOR (preferably with a science degree in zoology or a medical qualification) IN MICROANATOMY, to teach medical and science students and conduct research in embryology; and an ASSISTANT PROFESSOR IN GROSS ANATOMY, at Dalhousie University, Halifax, Nova Scotia, Canada—Prof. R. L. de C. H. Saunders, Canada House, Trafalgar Square, London.

LABORATORY TECHNICIAN (with a good background of hæmatological and allied laboratory technique, and preferably one "A" level science subject) IN THE RADIOISOTOPE DEPARTMENT, Victoria General Hospital, Halifax, Nova Scotia, Canada—The Nova Scotia Civil Service Commission, P.O. Box 943, Provincial Administration Building, Halifax, Nova Scotia.

LECTURER IN PHYSICS—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

LECTURER (with a degree in chemistry or pharmacy) IN PHARMACEUTICAL CHEMISTRY; and a LECTURER (with a degree in either botany or pharmacy) IN PHARMACOGNOSY at Kumasi College of Technology, Ghana—The Assistant Registrar, Kumasi College of Technology, 29 Tavistock Square, London, W.C.1.

LECTURER (with an M.D. or Ph.D. degree) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. M. Beznak, University of Ottawa, Ottawa, Canada.

RESEARCH ASSISTANT IN THE DEPARTMENT OF CHEMISTRY, for the study of high pressure solubility of gases in salt solutions—Dr. Norman O. Smith, Department of Chemistry, Fordham University, New York 58, N.Y., U.S.A.

RESEARCH ASSOCIATE (physics graduate, preferably with some knowledge of geology) IN THE SUB-DEPARTMENT OF GEOPHYSICS of the Department of Geology, to work on some aspect of rock magnetism —The Assistant Registrar (Science), The University, Edgbaston, Birmingham 15.

SENIOR LECTURER (qualified to direct research) IN PHYSICS—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

PHYSICS IN GRAMMAR SCHOOLS

PHYSICS D[illegible] [illegible]

THE recommendations of the Physics Panel of the Science Masters' Association and the Association of Women Science Teachers for new physics syllabuses for grammar schools in Great Britain[1] have three main points of departure from the usual run of school-teaching at the present time. A good deal of material which, on reconsideration, did not appear really fundamental has been discarded. Twentieth-century physics, including some of the most recent developments, has been included both in the Ordinary Level and the Advanced Level recommendations for the General Certificate of Education examinations. There has also been a determined effort to trace the development of the basic concepts as they are understood to-day—matter and energy, particles and waves—and to present the subject to the pupil as a unified study that probes the interchanges and interactions of these concepts from various points of view. They are, as yet, only recommendations; it will take some time before they crystallize into examination syllabuses, and probably still longer for them to establish themselves firmly in the curriculum—assuming that both of these consequences ensue. The Associations are, of course, hopeful that this will happen. If it does not, the chances of establishing an effective system of science teaching, within the next twenty years, seem remote. The recommendations are a 'breakthrough' in the original sense of the term, which means starting an attacking movement by finding an opening in the opposing side's defence—after, in this case, a long spell of safety play on the blind side. This metaphor is appropriate here, because the most enterprising breakthrough will lead nowhere unless it is supported by the rest of the team. Now is the time for all progressive teachers to come to the aid of the Panel.

The opposing side in this case is the aggregate of all the well-known difficulties that beset the teaching of science in schools; the reasons for believing that they can be outflanked will be given shortly. In addition, it must be frankly stated, there is a certain distrust in some university quarters of the capacity of the schools to manage anything except teach pupils to pass examinations. Views that have been expressed in this sense cover the whole range from deploring the efficiency of school instruction that anticipates most of the first two years of a university course, to writing off as a total loss most of what has been inadequately done at school and having to start again from scratch. To the university lecturers who may well say that the suggested new syllabus is adding to the factual knowledge milling around unco-ordinated in the undergraduate mind, and that they would prefer, instead of a nodding acquaintance with nucleons, a clear capacity to distinguish between an ampere and a volt, one would counsel patience. The recommendations are on their side all the way. For the whole object is to present physics in the middle school as part of the general education of all pupils, in a way that can be grasped; and to continue with advanced work for the future specialist in the same spirit, concentrating on the matter that is fundamental and can be readily understood. As Mr. J. L. Lewis has pointed out[2], the great beauty about studying radioactivity experimentally is the immense scientific content that can be extracted with very simple mathematics; and this is the sort of bias that the new syllabus has. There is a good chance that pupils may be really educated while they are learning, as well as passing an examination at the end of the process.

A good chance: But is it the best chance ? It has been said that, in aim, the recommendations are to some extent at variance with those of the Ministry of Education Pamphlet No. 38, which presents the study of science as a voyage of discovery[3]. Is the offering of facts and the establishment of modern concepts by lecture and film and sophisticated apparatus a substitute for simple first-hand investigation with primitive equipment ? Of course it is not. When teachers are as familiar with the new subject-matter themselves as they are with those topics which experience has shown susceptible to fruitful discovery-voyages (and there is not as wide a repertoire of these as one might think), the right methods will be developed to fit the material. There is no necessary incompatibility; it can be the best chance if we make the best of it.

The first part of the recommendations, covering the basic five-year grammar school course to be taken by all pupils, deals with fundamental ideas of mass and motion and force, the properties of solids and fluids, mechanical energy and heat energy, light and vision, vibrations and waves, electrical energy, atomic structure, and nuclear energy. It omits much that is of purely mathematical interest, such as resolution of forces, kinematic equations, problems on the laws of motion, and work on the inverse-square law. The wisdom of these omissions at this stage is apparent when one considers (*a*) the difficulty they cause, and (*b*) the resulting pictures in the young mind when they are eventually mastered. Later, it will be easy and appropriate to explain that there are convenient alternatives to the entirely general and sufficient principle of moments; that $\ddot{x} = f$ can be integrated; that Newton disclosed a little more than the magic formula $P = mf$; and that the inverse-square law is an essential geometrical property relating fields and particles in space, rather than something that works for sums that prove formulæ about magnets that must be learned as homework.

The second part, for the future scientist (and it must be remembered that very few people taking this sixth-form course will go on to do physics at the university, so that this is the general education of the scientist rather than the early specialization of the specialist), differs essentially from the present Advanced Level course chiefly in the emphasis given to vibrations and waves, to alternating current, and to modern physics, including such topics as the wave-particle duality of matter. But a good deal of purely memory work, and matter more appropriate to technology or applied mathematics, has been removed.

In an appendix, the essential ancillary mathematics has been tabulated, with the comment that this is what all scientists should be expected to master, and that it ought to be possible to cover it in two periods a week. It does not look too terrifying, and with the incentive to apply it to some really interesting physics it could be done.

Finally, it might be mentioned that the Associations have in active preparation (by their "Fourth Panel") sixth-form syllabuses for the general education of the non-scientist. Drafts are available for individuals who wish to see them for comment, but not for publication; and they have the same enthusiasm, the same sense of a pressing need, and the same realization of what can be achieved if it is seriously attempted.

We now come to the opposition. First, there is the admitted incapacity of very many physics teachers to branch out suddenly into new fields. The Panel says: "There are parts of the syllabus which some of us have never taught, and which we do not feel competent to teach. Universities and Technical Colleges are already arranging suitable short courses, and it is hoped that the Ministry of Education and local authorities will realize the importance of assisting in bringing teachers up to date". The widespread and regular running of such courses, starting immediately, would seem to be a first essential. It should be as much of a tradition for the science teacher to go back annually to the university as it is for the linguist to take his annual trip abroad, and all universities and places of higher education should participate in this. Next, there is the question of man-power available. The situation here is beginning to improve, and the new syllabuses should add appreciably to the attractiveness of school-teaching; the young graduate at present feels that he will never need to use his advanced knowledge in school work, and that it destines him for research. The realization that he will be extended, that he can still be a physicist as he understands the term, and that there are unlimited opportunities for research in the field of developing teaching methods and demonstrations, should attract a higher proportion of the best people. The co-operation of university physics departments in presenting this picture, which has always been valid to those who really understand what goes on in schools, could be offered with open eyes.

The matter of equipment would seem to require a combined operation. It would be easy, for a sum in the region of £500, to provide a nucleus of apparatus 'off the peg', which would enable a fair range of basic experiments to be done. It certainly exists, and some firms have specialized in apparatus for modern physics teaching. At the same time, many schoolmasters do not think along these lines, and prefer relatively simple home-made apparatus. Whichever way it is approached, the services of a technician will be not a luxury but a necessity; no such apparatus is 'school-proof', and maintenance and safety precautions in any laboratory equipped for proper teaching cannot be looked after by a full-time teacher. The alternative would be, of course, to use film, and film-strip, and film again . . . but teachers, who have taken the trouble to re-learn their subject in order to make it up to date and stimulating, are not going to be fobbed off with the cheap and easy way. For things such as counters and ionization chambers and gamma-ray sources there must, incidentally, be a good deal of equipment in Civil Defence stores that could easily and safely be passed over directly to schools; it seems to be almost a law of Nature that redundant apparatus must first pass to Government surplus dealers, where it stays because nobody can afford to buy it; but there must be some way of circumventing this in a good cause. The combined operation envisaged, however, is something at the highest level. The Ministry of Education, when it is decided whether these recommendations are desirable, should ask the Minister for Science to take over, and to arrange for the design and supply of suitable equipment. If it can be done for the training of Civil Defence wardens, it can be done for the education of the ordinary citizen.

It is difficult to forecast how the recommendations are going to work out in the matter of teaching time; though it is significant that several topics which lend themselves to a range of orthodox practical exercises, or to tedious mathematical proofs, have been omitted. It would appear that the syllabus has been lightened, particularly for the average sixth-former and for those who would at present be taking Ordinary Level physics as a separate subject. It remains, if the scheme is accepted, for the examining bodies and the teachers to interpret it in the spirit in which it has been framed.

PRELUDE TO SOCIOLOGY

Charles Booth

Social Scientist. By Prof. T. S. Simey and M. B. Simey. Pp. x+282. (London: Oxford University Press, 1960.) 30*s*. net.

CHARLES BOOTH (1840–1916), a Liverpool merchant and shipowner, who in his spare time and without any institutional or financial assistance surveyed the life and labour of the entire population of working-class London at the end of the nineteenth century, was indeed a heroic figure. Prof. and Mrs. Simey, in their very readable account of his life and work, have made out a good case for thinking that his contribution to the establishment of sociology on an empirical basis has been much undervalued. The mere magnitude of his achievement still leaves one dazed. To survey every single street, every court and block of buildings in the metropolitan area; to check on the resources of every family; to catalogue and describe every industrial enterprise; and in the final survey of religious influences to visit every chapel, church and social agency; to do all this with a handful of collaborators and with no modern methods of data processing was an incredible achievement.

Booth's survey, *Life and Labour of the People of London* (3rd ed. 17 vols. 1902–3) was the pioneer social survey. Nothing quite like it had been carried out before. Within the limits which Booth set himself it gave a factual picture of London working-class life which was vivid, unsentimental, accurate and detailed. The volumes on poverty, which indicated with irrefutable evidence that more than one-third of London's population were at all times more or less in want, changed our social policies, and led ultimately to the introduction of the Welfare State.

This, perhaps, has been recognized by social historians. The Simeys, however, claim more. Booth was also, they hold, a great social scientist, one of the founders of empirical sociology, and it is this aspect of his work that has been unduly neglected. Sociology before Booth was largely deductive. Booth insisted on the need for facts. "The *a priori* reasoning of political economy", he said in a paper to the Royal Statistical Society, "fails from want of reality. At its base are a series of assumptions very imperfectly connected with the observed facts of life. We need to begin with a true picture of the modern industrial organism". In his collection of facts Booth relied on a combination of two things: statistics and first-hand observations. Accurate statistics were essential to get the picture in objective proportion; but alone they could mislead, and first-hand observation was needed to add colour and life. To this end Booth went endless walks to see for himself; lived in cheap lodgings; personally attended hundreds of religious services; and filled endless notebooks with his impressions and observations. There is no doubt an important lesson here, which in a day of more plentiful statistics may be overlooked. Booth, perhaps, had too many facts. He worked before the introduction of sampling methods, and his theoretical apparatus was not strong enough to enable him to make a meaningful selection. Sometimes from the mass of data important working hypotheses and conclusions emerged, which led to practical action, as in the case of old age pensions, for which Booth was largely responsible; at other times Booth ended up with detailed descriptions from which nothing very conclusive could be derived. Some of the ingredients of a true science of society were still lacking in Booth's work. But no science is possible without facts, and Booth demonstrated in a new way and on a new scale what facts meant in the study of society. The Simeys have made out their case. Booth must properly be regarded as one of the notable pioneers of empirical sociology.

L. S. HEARNSHAW

ELASTIC SHELLS

The Theory of Thin Shells

By V. V. Novozhilov. Translated by P. G. Lowe. Edited by Prof. J. R. M. Radok. Pp. xvi+376. (Groningen: P. Noordhoff, Ltd., 1959.) 36 D. fl.: 9.50 dollars.

Proceedings of the Symposium on the Theory of Thin Elastic Shells

Delft, 24–28 August, 1959. Edited by W. T. Koiter. (International Union of Theoretical and Applied Mechanics.) Pp. ix+496. (Amsterdam: North-Holland Publishing Company, 1960.) 55*s*.

THE theory of elastic thin shells has undergone considerable developments in the past few years, and it is good to see two excellent books on the subject, one concerned to present the elements of the theory to a beginner and the other to mark some of the bounds of our present knowledge.

In *The Theory of Thin Shells*, Prof. V. V. Novozhilov develops the linear theory of the stress and displacement of thin shells in terms of the familiar assumptions of the classical Love–Kirchhoff theory, that normals to the middle surface of the shell remain normal after the displacement, and that stresses on surfaces parallel to the middle surface are small. The relevant parts of the geometry of surfaces are developed *ab initio* in a simple and lucid manner, which should be well within the compass of any engineering undergraduate. With this foundation, Prof. Novozhilov is able to present the elastic equations for a general shell in the simplest practicable form, and so to save the reader the trouble of following a number of separate derivations of equations for special shells. In the succeeding development of the theory, special place is given to the method of complex components, which has not been discussed satisfactorily in previous books in English. The later chapters, on membrane theory, cylindrical shells and shells of revolution, contain most of the important standard solutions in these fields, including those for reinforced cylinders. Special mention should be made of the section on the toroidal shell, which brings out the inadequacy of the membrane theory as a first approximation in this problem, and gives results in a reasonably compact form.

In all, this book can be recommended with confidence as a first course on the subject, and should also prove valuable to experienced workers in the field. The translation is very easy to read, and the type-setting is excellent.

For workers carrying out research on the subject, the proceedings of the symposium on the theory of thin elastic shells will be both stimulating and informative. The subjects of the papers were deliberately limited to problems involving either non-linear behaviour or two independent variables, and the volume has a unity of purpose not always found in a symposium. The papers range from a discussion of the basic approximations involved in a first-order theory of shells (W. T. Koiter) to solutions of particular problems of more immediate practical interest, like the "Bending at the Oblique End Section of a Cylindrical Shell" (A. van der Neut). A detailed discussion of the various papers is beyond the scope of this review, and would, in any event, reflect the tastes of the reviewer more than the importance of the contributions. Some of the work, for example, "On the Unsymmetrical Snapping of Shells of Revolution" (E. I. Grigolyuk) or the beautiful experimental results of W. Schell on the buckling of cylindrical shells, will probably become classical in the literature. Other papers, especially those on the general equations of equilibrium or motion, deal with issues which are still controversial, but pave the way for a more mature understanding of the whole subject at some later date.

The publishers are to be congratulated on the rapid and pleasing production of this volume, and the organizers of the symposium on bringing together so much useful work. J. W. CRAGGS

CELLULOSE PULP FROM WOOD

Pulp and Paper

Chemistry and Chemical Technology. By James P. Casey. Vol. 1: Pulping and Bleaching. Second edition, revised and enlarged. Pp. xix+675. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 147*s*.

THE first edition of this work, published in 1952, has proved so valuable to the industry that there is really little need for the author to justify the present edition by stating in his preface that ideas are changing faster than practice. A measure of the rate at which this is occurring may, however, be obtained from the fact that Volume 1 of the first edition, which dealt with pulping and bleaching and paper-making, now becomes two volumes, of which the first is now under review. Thus, there are now approximately 450 pages on pulp and 120 pages on bleaching, as compared with 250 and 70 before, respectively.

The plan of the book follows the same general lines as previously, but naturally developments which have come to the fore in the past ten years receive due attention in their appropriate places. These include continuous pulping methods, chlorine dioxide bleaching, magnesium-base liquor recovery, the removal of bark from trees by chemical methods, hardwood pulping, and whole wood-fibre (particle board) manufacture. The portions of the book which deal with these are valuable summaries of our knowledge of these important subjects existing to date. Numerous literature references are provided throughout (nearly 1,280 in all).

A criticism levelled in review against the first edition was the almost exclusive American outlook, especially in the literature references and in the treatment of those fibres other than wood which are not commonly used in the United States. This still applies. Thus one might well infer that there have been no advances in the manufacture of esparto, rag and straw pulps, since the sections involved are almost unchanged. Indeed the word 'recent' is used as in the first edition to describe work carried out in 1948. The sections on esparto, bamboo and rag are so sketchy as to be of little or no use to those interested in them; this will apply to many readers outside the United States. Furthermore, the erroneous attribution of low recovery in the straw process to the presence of silica (also pointed out in review) recurs in this edition.

However, it is evident that the author is writing primarily for the American reader, and presumably, therefore, sins of omission cannot be held too strongly against him. As a presentation from the fundamental point of view of up-to-date knowledge on the pulping of wood the second edition of this work will undoubtedly command the same high status as its predecessor. JULIUS GRANT

HETEROMETRY

Heterometry

By Prof. Mordechai Bobtelsky. Pp. viii+229. (Amsterdam: Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1960.) 42*s*.

THE heterometric method was introduced by the author, Prof. Mordechai Bobtelsky, of the University of Jerusalem, and the present monograph gives details of the varied and unique applications of this new technique in the fields of inorganic, physical and analytical chemistry. The heterometer was developed as an instrument for observing the instantaneous variations in optical density when a beam of light is passed vertically through a cylindrical absorption cell in which a heterogeneous reaction, for example, precipitation, is taking place. Colour interference is suppressed by placing suitable filters in the path of the light. Variations in the optical density are observed using a photometric cell, the solutions being stirred at a constant convenient rate. Since 1953, Prof. Bobtelsky and his co-workers have studied many thousands of reactions by means of this method. Heterometric titrations can give valuable information relating to the formation of primary or intermediate products during the formation of insoluble complexes, and can thus provide data which are unobtainable by ordinary turbidimetric measurements.

The combination of the heterometric method with the more classical applications of conductimetry and potentiometry are discussed for specific reaction systems. Considerable information is also provided indicating the quantitative analytical semi-micro applications of this new method, the determination of traces of a metal (0·1 per cent) being heterometrically possible even in the presence of more than 99·9 per cent of polyvalent foreign metals. Examples are extensively given of normal salt analyses and of the behaviour of many chelated metal ion–organic compound derivatives as recorded by heterometric analysis.

The final chapters of this monograph deal with the results of numerous researches on the formation of insoluble compounds in various solvents, for example, the metallic derivatives of aliphatic and aromatic dicarboxylic acids, and of allied derivatives of the oxycarboxylic acids, polyphosphate complexes, thio derivatives, interaction of metal salt solutions with dyestuffs, the study of heterogeneous chain reactions and the question of inorganic-organic polymer formation are all topics which are discussed by reference to much graphically illustrated experimental data.

This is the most authoritative compendium of heterometric research investigations which has so far been published, and will, undoubtedly, prove of the greatest utility to the research worker studying heterogeneous phase systems, as well as to the analytical chemist and the university teacher. This is a modern technique which may have much future application, and it is pleasing to note that heterometry forms one of the subjects to be presented at the eighteenth International Congress of Pure and Applied Chemistry in Montreal next August.

D. T. Lewis

ARCHÆOLOGY IN ISRAEL

Hazor II

An Account of the Second Season of Excavations, 1956. By Yigael Yadin, Yohanan Aharoni, Ruth Amiran, Trude Dothan, Immanuel Dunayevsky and Jean Perrot. With a contribution by S. Angress. (The James A. de Rothschild Expedition at Hazor.) Pp. xxiv+174+210 plates. (Jerusalem: Magnes Press of the Hebrew University; London: Oxford University Press, 1960.) 178*s.* 6*d.*

THANKS to the efforts of Dr. Yadin and his army of assistants, Hazor must be one of the most widely known of ancient Palestinian sites. Its importance lies not only in the outstanding interest of its excavated remains, but also in the fact that sufficient was known about the history of the city before the excavations ever began to enable these remains to be related to historical events, and to be dated accordingly with a fair degree of accuracy. In the second season of excavations work was concentrated in two areas on the *tell* proper, and two in the lower 'enclosure', which has now been proved conclusively to have been the site of the Canaanite town of the Middle and Late Bronze Ages, finally destroyed some time in the middle of the thirteenth century B.C. by (so Yadin thinks) the invading Israelites. In this lower city, the most important discovery has been that of a Canaanite shrine, with cultic objects (including a mask and a bronze standard) of outstanding importance for the history of Semitic art and religion, and also of other buildings which Dr. Yadin interprets (not very convincingly) as cultic. On the *tell* the chief buildings excavated were a fine pillared storeroom, attributed to Ahab; the Israelite citadel destroyed by Tiglath-pileser III of Assyria in 732 B.C.; and a casemated fortification wall probably built by Solomon. Individual objects from the *tell* included a beautiful marble incense ladle in the form of a hand, and several highly important Hebrew inscriptions. Space does not permit us to record here any more fully the discoveries of the archæologists. They are all now published lavishly, in this magnificent volume full of drawings, photographs and data, so that students in future will have no excuse for not knowing what has been found at Hazor.

They will, unfortunately, have far more excuse for not knowing exactly where it has all been found. In a review of the first volume of this report (*Nature*, 183, 951; 1959) I questioned the validity of the methods used by Dr. Yadin to unravel and interpret the complicated series of superimposed building remains at Hazor. The appearance of the present volume has, if anything, strengthened my belief that the analysis of the remains is not nearly as accurate and as detailed as it could be. This is the result both of a faulty method of excavation and of a faulty system of interpretation. The method is faulty because too much attention is paid to the levels of individual structures and surfaces, expressed in actual heights, and not enough to true stratigraphy. Where the floors are relatively and consistently level over a wide area, and the succession is regular, this may not matter too much; but such conditions are the exception rather than the rule. Where the ground slopes, and the ancient inhabitants have built on terraces, as they have in area *F*, for example, Dr. Yadin's method of excavation is fraught with danger. The confusion in area *F* is indeed great, and the reader (and, one suspects, the excavator) is quite at a loss to know which structures belong to stratum 1*A* and which to 1*B*. These uncertainties are, admittedly, openly acknowledged by the excavators, and Dr. Yadin is, no doubt, to be highly commended for allowing a member of his staff to publish a 'minority report' expressing serious differences of opinion, as M. Perrot does in a long footnote on p. 128ff.; but such differences of opinion do not inspire the reader with much confidence in the interpretation elsewhere.

This brings me to another point. For all the lavishness of illustration and documentation in this report, the record is still not full enough to allow the reader to form his own judgment about the meaning of the evidence presented. Prof. De Laet has well said (*Archæology and its Problems*, p. 52) that the test of a good excavation report is that the reader "ought to be in a position to reconstruct the whole excavation, almost every turn of the spade, in such a way that he can scrutinize most critically the conclusions reached by the author". The Hazor report fails this test. It is just as important that the reader should see for himself that one floor is higher or lower, and therefore later or earlier, than another, as it is that he should be given illustrations of the forms of Hebrew letters, to judge them for himself. The only way to illustrate stratigraphy is to publish accurately drawn and objective sections; and there is not one in this book. Without them, many of the fine plans are almost useless.

Finally, with regard to the faulty system of interpretation: does Dr. Yadin really want us to believe that all over his site the succession of superimposed floors and 'strata' is regular and orderly; that there was no local destruction and rebuilding; and that the structures under, for example, 'Stratum VI' always belong to 'Stratum VII'? Such is the general impression obtained from this report; though on p. 165 it is admitted that "certain layers in sub-areas which looked at first like real strata are in fact only local phases", while, in his footnote already mentioned, M. Perrot recognizes the presence, in area *F*, of "intermediate" strata, which, however, find no place in the neat synchronization table on p. 165. Such over-simplification is unrealistic, and detracts from the undoubted merits of the Israeli excavations at Hazor.

Peter J. Parr

THE ANATOMY OF MANAGEMENT

Exploration in Management

By Wilfred Brown. Pp. xxii+326. (London: William Heinemann, Ltd., 1960.) 30*s.* net.

The Attitudes of Steelworkers to Technical Change

By Olive Banks. (Social Research Series.) Pp. viii+152. (Liverpool: The University Press, 1960.) 25*s.* net.

THERE are few books that have been written by men who combine a wide experience of the practice of management with a developed system of ideas for the analysis of that experience. Mr. Chester Barnard's *The Functions of the Executive* was alone in eminence in this field until Mr. Brown wrote his latest book; but *Exploration in Management* will be as important in the study of organizations.

Mr. Brown's book has the sub-title *A description of the Glacier Metal Company's concept and method of organization and management.* This is most accurate, for the book is a report on the organizational relationships within that Company today and on the experience that has led to its structure. The book is in several parts, considering structure, policy formulation, communication, the organization of specialists and the sources of managerial authority. It gives us, in great detail, information about the problems that arise within an industrial hierarchy that adds much to our store of empirical knowledge.

Mr. Brown is primarily concerned with the problems of authority in organization; the clarification of superior-subordinate and collateral relations, and the attempt to reconcile the authoritarian concepts of mechanistic organization, writing with the wealth of understanding of human motivation in industry that stems from Elton Mayo, to which the Glacier Metal Company has contributed so much. This book is a part of the new trend in organizational theory in that it seeks a synthesis between these two ways of describing the social system of an organization, and Mr. Brown has developed specific mechanisms in the Company to limit and legitimate the use of authority. It is probably at this point that the book is weakest, for the concept of authority used is over-simplified and almost entirely defined in structural terms. Consequently, the compensatory mechanisms are also too simple and deceptively clear-cut. The Glacier Metal organization may, therefore, not be a generalized model applicable to all firms, or all similar firms, but it will be the stimulus to much new thinking in many.

Dr. Banks's book reports an extension of the previous work at the University of Liverpool on the social factors affecting technical change in a large steel works. She is concerned with an intensive analysis of the attitudes of steel workers to change, and her work is part of an international project. The European Productivity Agency has published a general report on the project "Steel Workers and Technical Progress" and the book under review represents the English contribution to this joint endeavour.

A questionnaire was administered to a sample of 278 men, all of whom had been affected by a major technical change some four years before the administration. The questionnaire was designed to elicit the attitudes of the workers to the specific changes they had experienced, in terms of wages, conditions, and social factors, and also to attitudes to change in general. The responses are analysed in terms of a naïve socio-economic theory, but, although there is some valuable information in this study of perceptions of social change recollected in tranquillity, there is little that could be used as the basis for prediction. The data need to be re-worked in terms of more sophisticated concepts of social structure and industrial motivation before their full value can be realized. There are, scattered in the text, important references to the role of management in this successful change; but the questionnaire is not designed to put dimensions on this apparently crucial factor. This is regrettable, for we might have had more field evidence to consider against Mr. Brown's hypotheses.

F. J. WILLETT

TERRESTRIAL CRUSTACEANS

Isopodes Terrestres (Première Partie)

Par Prof. Albert Vandel. (Faune de France, Nr. 64.) Pp. ii+416. (Paris: Éditions Paul Lechevalier, 1960.) 105 NF.

THE production of this valuable book could have been left in no better hands than those of Prof. Vandel, whose vast knowledge of the terrestrial Isopods represented by the sub-order Oniscoidea, has been collected into this comprehensive work.

The volume is divided into two sections: first an introduction, which contains facts of interest to the group as a whole, and secondly a systematic part dealing with some of the families of the Oniscoidea. In the first part the author outlines the history of the group, and then passes on to points of importance in the morphology of its members. These are dealt with under a number of headings: size, coloration, visual organs, integument (including ornamentation), sensory structures and cutaneous glands.

This is followed by an account of the segmentation of the body, the structure of appendages and sexual characters. A further section is concerned with geographical distribution and ecological factors and the origin and history of the Oniscid fauna of France. The first part ends with a survey of the principles of systematics and the classification of the Oniscoidea. The author points out that, of the twenty-one families, only members of thirteen, which are represented in the fauna of France, are considered in the systematic part. The latter begins with a key to determine these thirteen families, and it is unfortunate that in Section '*K*' of the key 'Armadillidae' occurs in error for 'Armadillidiidae', so that the former appears in both '*K*' and '*L*' sections.

The main body of the work represents a detailed account of the members of four of the families (Tylidae, Ligiidae, Trichoniscidae and Buddelundiellidae); the remaining nine families will be covered in the second volume. Each French species is dealt with under eight heads: synonyms, morphology, affinities, reproduction, parasites, ecology, geographical distribution, and palæontology. Keys for the identification of genera and species are included wherever applicable.

The book is profusely illustrated with clear, well-labelled drawings, as well as a number of distributional maps; it will be indispensable to the specialist and invaluable to ecologists and students not only in France but also elsewhere.

Chemical Analysis of Cast Iron and Foundry Materials

By W. Westwood and A. Mayer. Second edition, revised by W. E. Clarke and H. Green. Pp. 586. (London: George Allen and Unwin, Ltd., 1960.) 63*s*. net.

THE analytical methods presented in this volume have been thoroughly tested in the laboratories of the British Cast-Iron Research Association. Fully detailed instructions are given in each case, and the practical details are accompanied by discussion of the relevant theory. In all cases, a general survey of existing methods is given, and the relative merits of alternative procedures are considered.

In this second edition the revising authors have modified or replaced a number of methods, according to experience and the results of analytical research. Such research has yielded an interesting new scheme for the analysis of cupola slag. A complete analysis of this material can now be carried out in less than one working day, with an accuracy comparable with that obtained by classical methods.

The short section dealing with laboratory practice and apparatus now includes a description of separations by solvent extraction procedures. Instrumental methods receiving brief attention are flame photometry, polarography, spectrography and X-ray fluorescence spectrography. A description of a particular absorptiometer has been replaced by a general account of the basis of absorption spectrophotometry and of spectrophotometric instruments—a particularly sensible modification to the text.

The methods given in this book are capable of wider application than the title suggests. The clarity with which the subject-matter is presented makes it possible for the analyst to assess the applicability of the individual methods to general inorganic analysis, as well as to the analysis of all classes of ferrous materials. F. L. Selfe

Theoretical Elasticity

By Carl E. Pearson. (Harvard Monographs on Applied Science, No. 6.) Pp. xi+218. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1959.) 48*s*. net.

THE writer of this book states that its purpose is in part to discuss modern methods in elastic theory, and in part to provide a compact summary of such methods.

The first four chapters contain a detailed account of vectors and Cartesian tensors, and of their use in describing infinitesimal strain and stress. Chapter 5 gives a summary of the basic equations of classical elasticity, and Chapter 6 a useful and interesting account of the general methods of solution associated with the names Somigliana, Betti, Kelvin, Boussinesq, Papkovitch-Neuber, Galerkin and Maxwell-Morera. Chapter 7 describes variational methods, though without illustration or application. Chapters 8 and 9 deal with topics in thermoelasticity and time-dependent problems, and Chapter 10 gives a brief introduction to non-linear elasticity.

The treatment is somewhat uneven; elementary topics are treated at considerable length and advanced topics sketched briefly. Some references are given, but not always enough to enable the reader to find proofs which have been omitted by the author.

J. F. Baker

Physical Metallurgy of Stress Corrosion Fracture

Edited by Thor N. Rhodin. (Metallurgical Society Conferences, Vol. 4.) Pp. xiii+394. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 98*s*.

AN engineer of great experience has recently stated that in no less than 27 per cent of all cases submitted to him for investigation the primary cause of the failures was ascribable to corrosion in one form or another, and in the majority of instances while the metal was under stress. The papers presented to the symposium recorded in this book give a very good account of the present state of knowledge regarding stress-corrosion and add to what is already known. In view of the important role of the crystal boundaries in leading to such trouble, it is, for example, valuable to have clear proof that the effect can occur even in single crystals. Since, if a solution of this extremely elusive problem is to be found, it can only arise from fundamental work, it is appropriate that more than half the book is devoted to the more theoretical aspects of the subject. Of the more immediately practical papers, although the stainless steels receive most attention, both mild steels and non-ferrous alloys are considered. This is an excellent account of the complex phenomena concerned with stress-corrosion failures and may be recommended unhesitatingly. F. C. Thompson

The Cathode Ray Tube Memory of the High Speed Electronic Computer of the U.S.S.R. Academy of Sciences

By V. N. Laut and L. A. Lyubovich. Translated from the Russian by Ruth Feinstein. Edited by F. A. Sowan. Pp. xi+90. (London and New York: Pergamon Press, 1960.) 35*s*. net.

THIS book describes the 1,024 word store used in the *B.E.S.M.* digital computer, which operates in parallel with a 39-bit word-length at a pulse-rate of 80 kc./s.

The first two chapters include a block diagram of the store organization, and a description of the storage tube, a barrier grid type using an aluminium back plate which stores 1,024 bits of data as a pattern of electric charges. Chapters 3 and 4 cover the writing and reading circuits used with the storage tube, and the balanced bridge circuit which isolates the reading and writing amplifiers. Chapter 5 describes the decoding of the address digits, the generation of the appropriate storage-tube deflexion voltages, and gives a discussion of the accuracy and stability of the spot position. Chapters 6–8 deal with the control unit, including test facilities, the coupling to the main computer, and the initial setting-up procedure. The final two chapters deal with the mechanical aspect of the store, and its performance in service.

Since the latest reference is dated 1955, the original text was presumably written in 1955 or 1956, and the type of storage described is generally considered obsolete. It has indeed been reported that the *B.E.S.M.* computer was equipped with magnetic-core storage in 1959 to replace the cathode-ray tube store. Thus, although the book gives a comprehensive account of the design and operation of the store, it should be regarded as a contribution to the literature of electrostatic storage tubes, rather than an account of present-day practice in digital computer engineering. J. C. Cluley

FOUNDATIONS OF QUANTUM THEORY AND COMPLEMENTARITY

By Prof. L. ROSENFELD
NORDITA—Nordisk Institut for Teoretisk Atomfysik, Copenhagen

THE foundations of quantum mechanics were laid some thirty years ago. Thus, a whole generation has passed since these foundations were established, but for the new generation which is now coming up the situation is perhaps stranger still than it was for the physicists who had to struggle with those problems for the first time. The people who face a problem for the first time and have to think very hard to try to solve it have a more direct and lively impression of what is involved in the new ideas which bring about its solution. The next generation is presented with the finished work and often does not appreciate properly the difficulties that were involved in the solution of the problem. So it happened with relativity theory one generation after Einstein ; some people started then to raise doubts about the very principles underlying the general theory of relativity. This episode is now forgotten; but we see the same phenomenon happening with quantum mechanics. Young physicists are raising doubts about the correctness of the basic ideas of quantum mechanics, and try to do it better. These efforts are, I am afraid, rather futile, because they rest on a complete misunderstanding of the problem, on a lack of appreciation of the really very difficult conceptual situation which quantum mechanics presents to us. This situation is not something that depends on any free choice, about which one might have this or that opinion. It is a problem which is imposed on us by Nature. After all, the existence of the quantum of action is a law of Nature: it is not something we have invented, but an aspect of Nature we have discovered. This discovery created, when it was made, a very embarrassing situation, and quantum mechanics is, in fact, the answer which physicists after many years of effort have been able to give to this challenge of Nature.

The discovery of the quantum of action was made in connexion with properties of electromagnetic radiation. In order to have something definite before us, we can therefore speak about the situation in the theory of light or electromagnetic radiation, although exactly the same can be said of electrons or any other constituent of matter. According to the classical theory of electromagnetism, light or any electromagnetic radiation can be described as a field, in the simplest case a field endowed with periodicity in space and time; the element of radiation is thus represented by a plane monochromatic wave, that is, a field distribution which has strict periodicity in space, with a certain wave-length, and in time a certain period connected with the wave-length and velocity of propagation by the wave equation. In order to have this strict periodicity, the field must be spread out over the whole of space, and it must persist during unlimited time: a pulse which only exists during a finite time does not have a sharply defined frequency, but a whole spectrum of frequencies; likewise, a limitation in space of the 'wave packet' implies a distribution of wave numbers (or inverse wave-lengths).

Now, the discovery of the quantum implied that when radiation interacts with matter, as in the photo-effect or in the Compton effect, the amounts of energy and momentum exchanged in this interaction are not at all related to the distribution of energy and momentum in the radiation field, but are completely determined by the mechanical laws of conservation governing collisions between particles of definite energy and momentum ; in this picture, a monochromatic radiation is represented by a light quantum or photon, behaving like a particle the energy and momentum of which are proportional to the frequency and wave number of the radiation. Thus, one was here led to describe radiation by means of another classical concept, which had hitherto been applied only to matter: the concept of the particle, which represents a concentration of energy and momentum at a single point of space and at any single instant of time. This is also, like the monochromatic wave, an ideal conception, and it is the extreme opposite of the latter; in fact, the two are mutually exclusive. Yet, they are intimately related by the equations:

$$E = h\nu, \qquad p = h\sigma \tag{1}$$

which express the proportionality between the energy and momentum E, p, concentrated in the particle, and the frequency and wave number ν, σ, defined by the plane wave.

These are at first sight very paradoxical equations : they relate together characteristics of the radiation which are contradictory to each other, and yet both are necessary to account for all phenomena (for the interference of waves is just as fundamental a phenomenon of radiation as the scattering of photons). The coefficient of proportionality, Planck's universal constant h, appears in the equations (1) as the product of two physical quantities—the energy of the photon and the period of the wave—which relate to two descriptions of radiation that are mutually exclusive. Thus such a situation demands more than just a mathematical analysis. The mathematics are extremely simple, but the question is to understand what these simple equations mean, as they seem to combine things that are mutually exclusive. What we meet with here is actually a problem of logic: What are we to do when we are confronted with such a situation, in which we have to use two concepts that are mutually exclusive, and yet both of them necessary for a complete description of the phenomena ?

It is this logical problem which confers a very peculiar character on quantum mechanics. The situation was not quite the same with the relativity theory. Of course, in creating this theory, Einstein had also to make a very deep analysis of the fundamental concepts of space and time and of the relation between them, but although the result was quite revolutionary, he could perform this analysis within the framework of classical physics. Here we see that it is this framework itself that is too narrow logically: the task is to find a consistent way of using classical concepts so as to give well-defined meaning to mathematical relations like the equations (1) in spite of the fact that the parameters involved refer

---

* Substance of a lecture given at the University of Tokyo on October 6, 1960.

to two contradictory images. The solution of this problem, to which a fundamental contribution was given especially by Heisenberg, received its final formulation from Niels Bohr; the new logical instrument which was created by Bohr is called complementarity. Complementarity denotes the logical relation, of quite a new type, between concepts which are mutually exclusive, and which therefore cannot be considered at the same time because that would ead to logical mistakes, but which nevertheless must both be used in order to give a complete description of the situation.

The idea underlying complementarity and making t possible to surmount the logical contradiction is, n fact, very simple. Contradiction arises when one tries to give a universal validity to the concepts that are mutually exclusive. If one tries to apply both of them to any situation irrespective of the circumstances of the situation, then, of course, one gets into contradictions. However, if one reflects on the use of all physical concepts, one soon realizes that any such concept can only be used within a limited domain of validity. These limitations may be disregarded so long as one is dealing with simple situations, as in classical physics: the constant h, which marks the limit of applicability of classical concepts, is so small compared with the actions involved in macroscopic experiments that we can ignore the limitation. Therefore the physicists of the nineteenth century had no need to think very deeply about this question. But after the discovery of the quantum of action has confronted us with such a situation, we are forced to analyse the logical relations between concepts, and to recognize their limitations. But once one has realized the simple fact that every physical concept is only defined with respect to a certain class of phenomena, to certain well-defined physical situations, it becomes easier to understand that different sets of concepts, although incompatible, may nevertheless be applicable to different physical situations.

Domains of validity of complementary concepts are not, in practice, rigidly exclusive of each other; they may overlap to some extent. Where they overlap, the concepts in question can both be applied, but of course not rigorously. A well-known example is that of a 'wave packet' of radiation. There can be no rigorously monochromatic wave: a real wave is always limited to a finite time-interval, Δt, and a finite region of space, the dimension in one direction of which we shall denote by Δx; such a wave can be analysed into monochromatic components with frequencies and wave numbers (in the direction x) distributed over intervals $\Delta\nu$, $\Delta\sigma_x$, the order of magnitude of which, according to the mathematics of Fourier expansions, is just $(\Delta t)^{-1}$, $(\Delta x)^{-1}$. We may regard such a wave packet as approximating the localization of the phenomenon in time and space with latitudes Δt, Δx, and at the same time, because of the relations (1), fixing the energy and momentum of the radiation within an accuracy $\Delta E = h\Delta\nu$, $\Delta p_x = h\Delta\sigma_x$. Thus, between the latitudes of the complementary pictures there is a reciprocity :

$$\Delta E \,.\, \Delta t \approx h, \qquad \Delta p_x \,.\, \Delta x \approx h \qquad (2)$$

which is an example of the famous 'uncertainty relations' holding for any pair of physical quantities complementary to each other.

This reciprocity illustrates a fundamental feature of the complementarity relationship. On one hand, there is no absolute limitation to the possibility of defining either of the complementary quantities: by making the wave packet infinite we obtain the idealization of a photon of well-defined energy and momentum; by making it infinitely small we have the ideal localization of the radiation at a single point of space–time. On the other hand, when we approach either of these extreme idealizations, we see that the complementary one becomes less and less defined, and is finally excluded : the fixation of the energy and momentum of the photon precludes its localization, and conversely, if we localize the radiation field, we lose the definition of the energy and momentum contained in it. Such reciprocal limitations correspond, of course, to real physical effects, and the complementarity relationship just expresses the fact that the experimental set-ups required for the determination and recording of each of the quantities in question are such as to impose on the complementary quantity the lack of definition expressed by a relation of the type (2). To realize quite clearly what is involved here, we must sharpen our language and ask ourselves, more searchingly than was necessary in classical physics, what we understand by a physical phenomenon. The precise definition of a phenomenon must include the description of the apparatus which defines the conditions of the experiment, and also some recording process (an index reading, a spot on a photographic plate, etc.) by which alone the phenomenon can be regarded as terminated : the physical quantities we are dealing with in our mathematical theories are in fact just such records of phenomena. Phenomena so defined can be in a complementarity relationship, and the accuracies of their recordings then stand in a reciprocal uncertainty relation.

Reciprocal uncertainty relations are in fact precisely what we must expect, from a purely logical point of view, if we are, as in quantum theory, in a situation in which contradictory pictures of the phenomena have to be resorted to for a complete account. In order to avoid trivial mistakes which would arise from an indiscriminate use of such contradictory concepts, we must have some way of delimiting their domains of validity, some prescription enabling us to decide in each case how far we can go with the help of each of them. The uncertainty relations tell us, so to speak, the price we have to pay for applying to the description of a phenomenon two sets of concepts which are strictly contradictory. It will be realized, without going into further detail, that the conception of complementarity means a very considerable extension of our way of speaking about Nature and about natural phenomena. It involves a new logical framework within which to arrange our concepts, compared with which the classical way of speaking appears very narrow because it is confined to the simple classical logic, governed by the principle of contradiction. Of course the classical logic remains the foundation of any argument we use, and certainly of our mathematics. But we find that when we deal with quantum phenomena it is too narrow : we must have a wider way of connecting together the various concepts, and this is provided by complementarity.

The most considerable change in our view of natural phenomena which is implied by this widening of our outlook is related to our conception of causality. In classical physics the expression of causality is the result of the mathematical properties of the equations expressing the laws of motion of particles and of propagation of the electromagnetic field. When we are given the initial conditions, involving the initial values of the quantities and perhaps some of their derivatives, the solution of the equations is completely determined; and accordingly, the type of causality of classical physics is determinism. This is no longer the case when we have a complementary relationship, as is already suggested by the fact that we cannot then speak of all physical quantities with unlimited accuracy. One of the most obvious examples illustrating the new situation is the emission of the spectral lines: according to the quantum postulate, an atom in a high state of excitation can effect transitions to any one of the lower excited states; but there is nothing in the conditions of the phenomenon to tell us which of these possibilities will be realized in a definite case. Therefore, all we can do is to try to find the relative probabilities of their occurrence; it is just to cope with such situations that the concept of probability has been invented. The argument applies quite generally to all complementary situations; if we consider one set-up, in which, let us say, the field is localized within a certain space–time region, we have a probability distribution for all possible values of the energy and momentum, and conversely. These distributions are such that the corresponding average fluctuations are connected with the complementary time and space latitudes by reciprocity relations: if the field distribution is very narrow in time, it is very wide in energy, etc. In other words, the kind of causality that is implied by the existence of complementary relations between concepts is statistical causality.

As is known, statistical causality was introduced, historically, in dealing with the affairs of human societies or states, which are notoriously undetermined : that is the origin of the word 'statistics'. It was for the first time applied in physics in connexion with problems of atomic theory, though not those concerned with the individual properties of atoms ; it was introduced in thermodynamics, that is, in the study of the properties of very large systems of atoms, and later also of systems composed of a very large number of monochromatic waves of radiation. This occurred in the second half of the nineteenth century, when, of course, nobody dreamt of the possibility of such queer things as complementarity. At that time the justification for introducing statistical causality was simply this. We aim at a complete description of a gas as a mechanical system of molecules; but this could only be obtained if we could know at a certain time the exact positions and velocities of all the molecules of the gas; then we could solve, at least in principle, the mechanical equations for the system, and deduce in a unique, deterministic way the state of the gas at any future, or past, time. However, this ideal aim is obviously unattainable, and therefore the best we can do is to speak of the states of the system in terms of probability, just as, in view of the impossibility of predicting the exact time of a man's death, we speak of the probability of his living for so many years.

The concept of probability was thus used with a sort of apology, in default of something better. This attitude was of course quite natural for people believing in determinism, believing that the Creator had imposed on Nature, once for all, rigid laws that had to be obeyed and were so contrived that they could only yield a single, predetermined, result. Unprejudiced observation of the world around us, however, will soon reveal that this idea of rigid determinism is a fiction, an unwarranted extrapolation from a very limited experience, and that there is no real justification for it. On the contrary, if we want to describe immediate experience, surely we must say that all our judgments about Nature or about ourselves are judgments of probability: we are never in a situation in which we know all the conditions for applying laws which would give us a unique answer. Thus, statistical causality appears in fact as more natural, more directly adapted to our actual needs than determinism; and it is much better to look at determinism as a limiting case of statistical causality, corresponding to statistical distributions very sharply peaked around the average values. From this point of view we are better prepared to accept the fact that the type of causality of quantum mechanics is fundamentally statistical; and we are even in a position to give exactly the limit of validity of classical determinism: the statistical deviations from classical behaviour become negligible in phenomena involving a large number of quanta of action.

Now, returning to the case of statistical thermodynamics, it is instructive to consider an objection to the point of view just outlined which is still often heard. It is all right to say that statistical mechanics is a self-contained theory, as I have tried to suggest; nevertheless it is conceivable that, if not human beings, at least imaginary beings, which Maxwell and his friends called demons, could be so small (and yet endowed with sense organs similar to ours) that they could observe the motions of the individual molecules of a gas; such beings could then give a deterministic description of it. I think the answer to this was already given very pointedly by Clausius, when Tait tried to use this fiction of the Maxwell demon to question the universal validity of the second law of thermodynamics by pointing out that those demons could bring about situations contradictory to the second law. Clausius's answer was: "We are not concerned with what demons can do, but with what heat can do by itself", which clearly means: with the phenomenon of heat which we can observe. I think there is a very deep truth in that answer, deeper perhaps than Clausius himself could realize at the time.

In fact, what the situation in quantum mechanics has helped us to realize is that science is primarily concerned with the communication of experience about phenomena, in other words, with statements made by human beings, and which other human beings are able to understand. For this very reason all such statements must make use of the concepts of classical physics, because classical physics is just the language describing the results of direct observation, the phenomena which we can observe with our senses, either directly or with instruments to increase the sensitivity, in any event, with recording systems composed of many atoms. If, then, we talk in this language about atoms which do not follow the laws of classical physics, we meet with the limitations of its use expressed by relations of complementarity. We thus see that this complementarity has its source just in the peculiar situation in which we find ourselves, as macroscopic systems, trying to describe the possible macroscopic interactions of our apparatus with the smallest elements of which Nature consists.

Now, if we look back at thermodynamics from this point of view, we see that it presents a logical problem which is just the same as that of quantum mechanics. Here also we are trying to describe atomic structures in terms of macroscopic concepts, and we may do this in two different ways; we may be able to give a more or less detailed dynamical description of the atomic system, in terms of the motions of its parts; or we may describe its state in terms of the macroscopic quantities, such as volume, pressure, temperature, entropy, which are related by the laws of thermodynamics. Between these two modes of description there is a relation of complementarity; this is very clear if we consider the temperature and the energy, representing the thermodynamical and the dynamical points of view respectively. These two quantities are complementary to each other in the sense that if a system has to have a well-defined energy, it must be thermally isolated, and we cannot then ascribe to it any temperature, because in order to define the temperature we must establish thermal contact between the system and another, very large system, serving as a thermostat; conversely, if the temperature of the system is defined in this way, it exchanges energy with the thermostat, which means that its energy is not determined; in fact, we know that in this case this energy has a definite statistical distribution, the canonical one, the modulus of which is proportional to the temperature of the system.

This complementarity we can formulate in a more general and precise way, in wide-going analogy with the case of quantum mechanics, by setting up reciprocal relations between the statistical fluctuations affecting macroscopic quantities. Of course, the reciprocal limitation of the dynamical and thermodynamical modes of description has nothing to do with the quantum of action: the similarity of the two cases is on the logical level only; physically, they are completely independent of each other.

The fluctuations we are here considering are those which affect the macroscopic parameters defining the state of a system which is a small part of a larger, but finite, system; then, even intensive quantities, like the temperature, will exhibit fluctuations, for they are only exactly defined for infinite systems. It is easy to see that one must expect reciprocal relations between fluctuations of extensive and intensive quantities, that is, those quantities which (for a homogeneous system) are proportional to the number N of constituent elements of the system, and those which are independent of N. In fact, the fluctuation of an extensive quantity, the energy, for example, is proportional to $N^{1/2}$, while that of an intensive quantity, the temperature, say, is inversely proportional to $N^{1/2}$; the product of the two is therefore independent of N and cannot be made arbitrarily small by a change of the number of degrees of freedom of the system. A more detailed calculation shows that the products in question are of the form kC, where C is a quantity independent of the size, but depending on the physical properties of the system considered, and k is Boltzmann's universal constant. Thus, it is this constant which here plays a part analogous to that of Planck's constant in quantum theory: it is inversely proportional to Avogadro's number, which is thus seen to define a critical size of the system, for which the complementarity between dynamical and thermodynamical description becomes important.

This consideration is not as artificial as it may seem: it is easy to give examples of systems of this critical size, which can be considered from both the dynamical and the thermodynamical points of view. If we take as the systems under investigation droplets of emulsion distributed under gravity in a solution, we have a case in which the systems are large enough for us to see them and to follow their motion, which is a Brownian motion, and yet small enough for us to speak of their statistical distribution in the solution. As a representative thermodynamical quantity we may take the entropy S, which will fluctuate on account of this statistical distribution of the droplets. Now we need an intensive quantity characteristic of the individual motions of the droplets; for this let us choose the velocity v, which is subject to the well-known Brownian fluctuations due to the collisions with the molecules of the solution. A simple calculation gives in this case for the product of the two fluctuations:

$$\Delta S\,.\,\Delta v = kv_0$$

where v_0 is a quantity of the order of the mean atomic velocities inside the droplet. We see that the pattern of complementarity applies to the present case in all details just as in quantum mechanics.

So far, therefore, we have found that the atomistic view of the world involves in its description two stages of complementarity. The first and most fundamental one occurs in the account of the properties of individual atomic systems, the second when we want to describe the behaviour of systems of large numbers of atoms. In the first case, a relation of complementarity exists between two sets of concepts which were used indiscriminately in classical theory: the space–time localization and the energy-momentum balance; it becomes significant when the mechanical action in the process considered is of the order of Planck's constant. At the second stage, we have complementarity between the dynamical and the thermodynamical behaviour of large systems, the critical size being given by Avogadro's number. In both cases, as we have seen, complementarity essentially implies a specific kind of statistical causality.

Let us now venture for a moment into the field of biology. We here meet with a very peculiar situation: what characterizes the biological behaviour, in contrast with the behaviour of inanimate matter, is the existence of a certain structural order, either definite spatial structures such as those of the protein molecules, or more formal, topological structures such as the interconnexions of nerve cells in the brain. In any event, we notice the appearance of some kind of order which has a remarkable stability, and which can be reproduced. Now, the great event of the past few years has been the discovery, at the very lowest stage at which the phenomena of life appear, of possible mechanisms by which the maintenance and perpetuation of such a type of order can be understood in simple terms of physics. There is certainly no reason to expect that, with the most elementary, also the most elaborate forms of biological behaviour will not eventually be reduced, in a certain sense, to the laws of physics and chemistry, that is, in the last instance, to quantum mechanics, since according to the famous saying of Dirac quantum mechanics explains a large part of physics and the whole of chemistry. Now we may perhaps add: the whole of biology.

Yet this is not the whole story. It is quite obvious that, when we are presented with such complicated structural problems, it is practically impossible, even with the most perfect knowledge of all the laws of physics and chemistry, to predict what kind of organism will result from a given structure of such complexity. We are here in the same situation as somebody who would know all about mechanics and is presented with a blueprint of some machine which he has never seen and which he does not know. It would be very hard for this person to guess the function of the machine, to understand why this particular combination of motions has been set up. We must realize that in order to get complete understanding of organisms we need the concept of function. We must somehow know beforehand what the function of a certain organ is in order to be able to understand its structure. We here meet with another type of causality, functional causality, which is obviously complementary to the ordinary causality of physics and chemistry, from which this concept of function is absent. Thus, we see that at the biological level we have another stage of complementarity, which again presents the same characteristics of mutual exclusiveness as the previous ones: on one hand, we have the complete description of organs in terms of physics and chemistry, on the other the functional mode of description, which will always be necessary for a complete account of such complicated arrangements of molecules as living beings. This complementarity is concerned with another aspect of atomic systems than just the size, although the size is rather critical, inasmuch as biological structures can only occur at a definite stage of molecular complexity, allowing on one hand for the necessary stability and on the other for the possibility of reproduction; but the main point here is the type of spatial ordering of the constituent atoms, which distinguishes biological systems from inanimate ones.

At this point I may perhaps be allowed to venture a little further still on the path of speculation, and raise the following question. The whole point of the logic of complementarity, in its application to the atomistic description of the world, is that the mutual limitations in the use of the classical concepts it implies, at each of the three stages we have recognized, are related in the last resort to the size of the sense organs of human beings. To be sure, there is no direct reference in physics or even in molecular biology to the human observer as such, but only to registering appliances which are entirely controllable physical systems. Still, the size of these appliances is dictated by the requirement that the complementary limitations be negligible in the account of their behaviour, and this effectively brings them to macroscopic size, that is, to a size adapted to our sense organs. There was a Greek philosopher, the sophist Protagoras, who used to say that "man is the measure of all things". There is a deeper truth in this than he could possibly fathom. This brings us to the question: Is the recourse to complementarity logic so to speak an accident, another of the many imperfections of human nature, and is it not conceivable that other rational beings, some kind of Maxwellian demons, could develop a different mode of description of Nature not affected by any complementary limitations ?

The tentative answer I should like to submit is that there is nothing more accidental in the emergence of complementarity logic than in the emergence of man himself as a product of organic evolution. My point is that the concept of a thinking Maxwellian demon is self-contradictory. I suspect that the development of a computing and communication system like our brain demands about that complexity of organization which has been reached by our own species in the course of evolution. After all, it is an empirical fact that rational thinking has only arisen at the stage of mankind, presumably because it was only at this stage that a brain developed with a sufficient number of interconnexions between nerve cells to make possible this very peculiar behaviour which we call rational thinking. Hence the suggestion that no animal other than man or some being of equivalent complexity can possibly have any physics; and this degree of complexity, as we have seen, necessarily implies the introduction of complementarity in physical theory.

The view of physics, and in fact of science, which results from the development of quantum theory is very different from the scientific ideal of the nineteenth century; but it is by no means, or so it seems to me, inferior to it. The ideal for which such people as Huxley and Tyndall fought, the supremacy of human reason over all forms of irrationality, was based on the deterministic view of a Nature governed by inflexible laws, which the task of science was to discover and to formulate. These laws, by their very nature, would have absolute validity, and they would give a picture of the universe, in the literal sense of the word, a picture which could be contemplated, but from which the spectator, the human spectator, would be excluded, or at least reduced himself to an object of contemplation. The present conception, on the contrary, stresses the fact that at every stage the human observer intervenes in a very fundamental way by determining the very language in which the laws of Nature are formulated. The significance of the laws of Nature, from this point of view, is not that of drawing a picture of the world independent of who is looking at it, but rather of giving an analysis of the interaction between ourselves and the external world. At first sight it would seem that one thus introduces in science a subjective element. But the fear that the objectivity and rationality of the old view would be abandoned is entirely unfounded. True objectivity is simply the possibility of guaranteeing that the account of the phenomena will convey equivalent information to all observers, that it will consist of statements intelligible to all human beings. This objectivity is indeed ensured in quantum theory by the existence of transformations which allow you to pass at will from the point of view of one observer to that of another, who makes some other type of experiment. It is just the invariance of the laws of physics for such transformations that guarantees their objectivity, and nothing is changed in this respect by the advent of quantum theory.

Far from marking a retreat of human reason from the ambitious aim of the great pioneers of the preceding centuries, the new ideal of science appears as a tremendous advance towards this very aim. Compared with the old one, it is much broader of scope, much richer of content. It is more truly adapted to the actual situation that scientists have to face in their quest; the logic of complementarity enables us to cope with the dilemmas which this situation presents to us, and which were insoluble from the old point of view. I may therefore conclude on an optimistic note by assuring the younger generation that the instrument of rational analysis we are handing over to them contributes to a further increase of our power of understanding our position in Nature and of coping with the problems which it raises.

COMETS AND THE FORMATION OF BIOCHEMICAL COMPOUNDS ON THE PRIMITIVE EARTH

By Prof. J. ORÓ

Chemistry Department, University of Houston, Houston, Texas

INTERACTIONS of comets with the Earth or the Moon have been suggested by Urey[1], Fensenkov[2] and more recently by Whipple[3] in order to explain several terrestrial phenomena. It is estimated that about 40 million comets are now present in the solar system[4], and it has been calculated that about 100 comets have collided with the Earth since the formation of our planet some 5×10^9 years ago. (The value of 100 comets is obtained from Urey's comet-Earth collisional probability assuming a constant rate of comet formation. This value would be larger if the number of comets when the solar system was formed were several thousand times greater than at present[4].)

I suggest that one of the important consequences of the interactions of comets with the Earth would be the accumulation on our planet of relatively large amounts of carbon compounds which are known to be transformed spontaneously into amino-acids, purines and other biochemical compounds.

First, the amount of cometary matter (made mostly of carbon compounds) trapped by the Earth during its first 2×10^9 years can be calculated to range from 2×10^8 to 1×10^{12} tons on the basis of Urey's collisional probability[1] and the estimates of 1–10 km. for the diameter, and 0·01–0·05 gm. cm.$^{-3}$ for the density of the nuclei of comets[1,5]. The assumptions made here are that most of the cometary matter, neutral or ionized, was retained by the gravitational and magnetic fields of the Earth, and that the Earth's environment during the first 2×10^9 years was essentially reducing[6] and perhaps abiotic[7,8]. It is further considered that the high temperatures developed as a result of the collision impact would not essentially have altered the potential reactivity of the chemical species present in comets, since spectroscopical observations of pre- and post-perihelion emission[5], and chemical experimentation[9–11], attest to the thermal stability of the cometary carbon compounds. The high pressures developed on impact would, if anything, tend to condense the monocarbon species into linear chains of 2–6 carbon atoms[12].

Secondly, if terrestrial accretion of cometary matter from comets passing sufficiently close to our planet is considered, the amount of carbon compounds trapped by the Earth would be even larger. It is possible that this second mechanism of mass transfer which would result in a more continuous accretion of cometary matter was as important as the one by direct collision. Analogous mechanisms to those above have been offered for the terrestrial capture of non-volatile meteoric matter[3,8,13–15].

Thirdly, it is known from work on cometary spectra carried out for more than half a century and compiled by Swings and Haser[5] that comets contain large amounts of hydrogen, carbon, nitrogen and oxygen compounds, as indicated by the fluorescence emission bands of diatomic and triatomic radicals or molecules such as CN, CH, CH_2, C_2, C_3, NH, NH_2 and OH, and ions such as CH^+, OH^+, CO^+, N_2^+ and CO_2^+, observed in the heads or in the tails of comets when these bodies are at distances of less than 3 A.U. from the Sun. The CN band is generally the first molecular emission to appear on the tails of comets during the travel of these bodies toward the Sun, and it is also the band with the largest degree of extension into the comets' heads, followed in intensity by the C_2 and the C_3 bands. It is possible that the nuclei of the heads of comets contain frozen free radicals which are volatilized by radiant heat from the Sun[16,17], and it is also possible that they contain frozen ordinary molecules which are vapourized and photodissociated into radicals by the solar radiation[5,18]. These two points of view do not necessarily exclude each other, since it has been found recently that the NH radical can coexist with reactive carbon compounds[19]. In general, it is considered that the parent molecules of CN, NH_2 and OH are hydrogen cyanide or cyanogen, ammonia and water, respectively[5,18].

On the basis of the above considerations, it would be of interest to find out by experiment the products formed from chemical mixtures approaching cometary composition. This has partially been done by studying the products formed in reaction mixtures containing hydrogen cyanide, ammonia and water. Recent studies in my laboratory have provided evidence for the synthesis of adenine[20,21], 4-amino-imidazole-5-carboxamide, 4-aminoimidazole-5-carboxamidine and formamidine[22], and glycinamide, glycine, alanine and other amino-acids[23] from the reaction of hydrogen cyanide in aqueous ammonia. All these compounds and other unidentified products were formed more or less simultaneously in the same reaction mixture in a spontaneous manner. More than fifteen experiments have been carried out to the present time using concentrations of hydrogen cyanide of 1 to about 11 *M* and temperatures of 30–100° C. The synthesis of adenine, imidazoles, amino-acids and the other compounds has been demonstrated every time that the reaction product has been analysed for them.

In addition to hydrogen cyanide, ammonia and water, other reactive molecules such as formaldehyde, acetaldehyde, hydroxylamine and hydrazine could be expected to be formed by intercombination of cometary radicals. Experiments carried out with aqueous solutions of these compounds have also resulted in the formation of biochemical products. Thus, formaldehyde and hydroxylamine or hydrazine have yielded amino-acids, amino-acid amides and aliphatic acids[24–26]. Formaldehyde in the presence of calcium oxide is known to yield C_3 to C_6 monosaccharides[27]. Recently the synthesis of deoxyribose from formaldehyde and acetaldehyde has been observed for the first time in my laboratory[28].

Since glycine and glycinamide were two of the most frequent products obtained in the above amino-acid synthesis, the polymerization of these compounds in aqueous ammonia systems was also studied. They were both found to give polypeptides which were characterized as polyglycines I and II by the infra-red spectra and chemical properties[29,30]. It may be added here that the synthesis of pyrimidines, such as uracil and cytosine, should also be possible by reaction of urea with certain C_3 compounds resulting from the symmetrical C_3 species of comets.

The mechanisms of synthesis of most of the above compounds have been elucidated, and in general follow lines in common with known chemical and biochemical syntheses. They have been briefly reported[31–33], and they will be published in detail elsewhere.

From the foregoing it appears reasonable that a large number of compounds of biochemical significance such as amino-acids, polypeptides, purines, pyrimidines, imidazoles and the pentoses, ribose and deoxyribose could have been formed from cometary matter trapped by the primitive Earth.

The present hypothesis of cometary origin of biochemical compounds on the primitive Earth is not to be considered as an alternative hypothesis to that formulated by Oparin[34], Urey[35] and Miller and Urey[36] and others, but rather as a complementary one since in both cases essentially reducing conditions for the primitive Earth's environment are assumed. This assumption of reducing conditions, or at least non-oxidizing, is borne out by geochemical evidence[6].

It can thus be visualized that after the Earth was condensed to approximately its present volume, having lost practically all the gases of the protoplanet's atmosphere[37–40], collisional and non-collisional mass transfer from the comets resulted in the accumulation on the Earth of significant amounts of reactive carbon compounds, which were mixed with similar, but perhaps less-reactive, compounds of magmatic origin[41,42], forming the early atmosphere and hydrosphere where organo-geochemical syntheses took place.

An important feature of this hypothesis is that it gives a plausible mechanism for the partial replenishment of the Earth's atmosphere by the continued accretion of gaseous compounds on the planet after all the Earth's original gases had escaped.

A second feature is that cometary collisions would lead to the concentration of relatively large amounts of carbon compounds in isolated regions of the primitive planet, making it irrelevant to the central biopoietic problem the extent of replenishment of the Earth's atmosphere. It need only be realized that a single comet would be equivalent to more than one million tons of organic matter, and that the effective concentration in the vicinity of the impact area would presumably be quite large due to the limited dilution caused by the small amount of water thought to be present on the primitive Earth[41,42].

A third, and perhaps most important feature, is that the reactivity of the chemical species present in comets and trapped by the Earth would be such that, under the increased gravitational field, and the other physical conditions developed on capture, they would be rapidly transformed into organic and biochemical compounds without the need of additional sources of energy ; making the synthesis possible even if the energy input from electrical discharges, ultra-violet light, ionizing radiation and magmatic processes were limited.

As a final thought it is interesting to note that the predominant elementary composition of comets, and for that matter that of the Universe as a whole if we exclude the inert gases[43], is precisely identical to the elementary composition of proteins, that is, hydrogen, carbon, nitrogen and oxygen. The corollary is that given appropriate planetary conditions[44], the phenomenon of biopoiesis should be a probable event in our universe rather than a very improbable one.

In order to formulate more precisely the quantitative aspects of this hypothesis it will be necessary to carry out more detailed work on the statistics of the cometary population of the solar system, on the chemical composition of comets, and on the nature of the dust cloud about the Earth.

I wish to thank Drs. L. F. Biermann, G. H. Herbig, H. C. Urey and F. L. Whipple for valuable information.

The experimental work on the synthesis of biochemical compounds reported here has been supported in part by grant *G*-13117 of the National Science Foundation.

OBITUARIES

Lord Stopford, K.B.E., F.R.S.

John Sebastian Bach Stopford was born near Wigan on June 25, 1888, and died on March 6, 1961, at Arnside, Westmorland.

He was educated at Liverpool College, Manchester Grammar School and the University of Manchester, graduating M.B., Ch.B. with honours in 1911, after gaining several distinctions and prizes during his medical course. After serving as a house surgeon at Rochdale Infirmary and assistant medical officer at Manchester Royal Infirmary, he became, in 1912, a demonstrator in anatomy in the University of Manchester. He was promoted lecturer in 1915 and in the same year he received the degree of M.D. with a Gold Medal for a thesis of outstanding merit on "The Arteries of the Pons and Medulla". He succeeded to the Manchester chair of anatomy in 1919 on the resignation of Prof. (later Sir) Grafton Elliot Smith, and in December 1934 he was appointed vice-chancellor in succession to Sir Walter Moberley. He combined his duties as vice-chancellor and professor of anatomy until 1938, when he resigned his chair and was appointed to a personal chair of experimental neurology.

His ability as a scientist was recognized by his election to the fellowship of the Royal Society in 1927, and he was the first Manchester medical graduate to achieve this high honour. Under the inspiration of Elliot Smith, his research work was predominantly neurological, and he collaborated successfully with his surgical colleagues (Sir Harry Platt, Sir Geoffrey Jefferson and Profs. E. D. Telford and John Morley) in the elucidation of various problems. His work can be divided roughly into three phases—his investigations on the blood supply of the brain, his anatomical and clinical studies on sensation, based mainly on the observation of many patients with peripheral nerve injuries, and his researches on the structure and function of various parts of the autonomic nervous system. He published more than sixty papers and an important monograph on "Sensation and the Sensory Pathways" (1930), besides contributing sections to several anatomical text-books. As vice-chancellor he was unable to indulge his flair for correlating basic and clinical research, but had he continued as a scientist he would undoubtedly have enhanced his already high reputation.

In a short notice one cannot even mention all that Stopford did for education and his University; but he was the best vice-chancellor Manchester has ever had and according to Sir Hector Hetherington (1956) "the best of us all" (the "all" refers to the members of the Committee of Vice-Chancellors and Principals). His worth was recognized nationally by his appointment as chairman, vice-chairman or member of such influential bodies as the General Medical Council and the University Grants Committee, the Commonwealth Fund, the Nuffield Foundation, the Interdepartmental Committee on Medical Schools, the Universities Bureau of the British Empire and the Council of the Royal College of Physicians, while locally he served as chairman of the Manchester Regional Hospital Board (1948–53), of the John Rylands Library, of the Royal College of Music, and on many other bodies. He was awarded honorary degrees by the Universities of Dublin, Leeds, Cambridge, Liverpool, Durham and Manchester, and honorary fellowships by the Royal College of Physicians and Royal College of Surgeons. He was knighted in 1941, created a K.B.E. in 1955, and he was included in the first list of life peers (1958).

He was a fine and imaginative teacher who helped to rescue anatomy from the topographical morass into which it had fallen, and who did much to close the gap which had developed between the basic medical sciences and clinical practice. He was a pioneer in the use of radiological methods in teaching living anatomy, and he was the first to take over from physiology the full responsibility for teaching histology. Both as a professor and vice-chancellor his sympathy with students and their problems was evident; and he was appreciated as highly by his colleagues in the Arts and other Faculties as by those in his own profession. His familiarity with education and research in all their manifold aspects was utilized, as the abbreviated list of his appointments given above indicates, by many Government and other bodies; and he was the chief inspiration for many of the far-sighted reforms in medical education recommended in the Goodenough Report.

He married Lily Allan, another Manchester medical honours graduate, in 1916, and they had one son. Theirs is the greatest loss; but those who served under him honour the memory of a distinguished scientist and supreme administrator and marvel that one who had gained so many honours could yet remain so human, humble and kind.

G. A. G. Mitchell

Miss Ethel F. Bellamy

The death of Ethel F. Bellamy on December 7 at the age of seventy-eight removes one of the last of those self-trained and dedicated workers who have done so much for astronomy and seismology in Great Britain. Miss Bellamy went to the Oxford University Observatory in 1899 as a personal assistant to her uncle, the late F. A. Bellamy, and was able to relieve him of some part of the work in the preparation of the Oxford zones of the *Astrographic Catalogue*. On the completion of these zones and under the direction of Prof. H. H. Turner, Miss Bellamy then undertook the reduction of the measures for the Vatican zones, work for which she was awarded a commemorative silver medal by the Pope in 1920.

At the end of the First World War, Prof. Turner had agreed to continue at Oxford the seismological work of John Milne. Miss Bellamy assisted Turner, and in this connexion spent some months in 1919 at Shide in the Isle of Wight in charge of Milne's instruments. This responsibility she continued when the improved Milne–Shaw seismographs were transferred first to the Boys's basement in the old Clarendon Laboratory and ultimately in 1928 to the University Observatory itself. Her great contribution to seismology lay, however, in the preparation of the *International Seismological Summary* (prior to 1923 the

Bulletin of the British Association Committee on Seismology). Her part was to collate the readings, in some cases measuring the original records, of earthquakes as recorded initially by 200, afterwards nearly 600, seismological stations throughout the world, and to maintain year after year a correspondence with these stations which did much to improve the accuracy of time-keeping. Originally, Turner computed the epicentres from these collated readings, but from 1923 a greater and greater part of this work was taken over by J. S. Hughes, now the director of the *International Seismological Summary* at Kew. From these epicentres and the computed residuals for each station Miss Bellamy then prepared the copy for the press and read the proofs. This work she continued until the transfer of the *Summary* to Kew in 1946, adding to it during Hughes's war service the computation of the epicentres for six quarterly issues of the *Summary*. Time also was found to prepare a catalogue of epicentres from the *International Seismological Summary* for the years 1925–30, and in 1936 a complete *Index Catalogue of Epicentres* for the years 1913–30 (Isle of Wight County Press) together with a frequently reproduced equal-area map showing the location of these epicentres on the Earth's surface. A brief account of this work with some of the original maps appeared in *Nature* (143, 504; 1939).

Dogged throughout her life by ill-health and working in discomfort for many years in an old wooden hut in the Observatory grounds, nothing was ever allowed to stand in the way of the quality and quantity of her work. It was only fitting that she should have been awarded an honorary M.A. by the University of Oxford, whose faithful servant she had been for so many years. Retiring in 1947, she spent her last years in Upwey, near Weymouth.

H. H. Plaskett

NEWS and VIEWS

Element 103, Lawrencium

The creation of lawrencium, the eleventh new man-made element beyond uranium (element 92), was announced on April 13 by the University of California and the U.S. Atomic Energy Commission. An isotope of this element was formed on February 14 by bombarding 3 µgm. of californium (element 98) with boron-10 or boron-11 nuclei in a heavy-ion linear accelerator at the Lawrence Radiation Laboratory of the University of California; the four nuclear scientists who carried out this experiment, Drs. A. Ghiorso, T. Sikkeland, A. Larsh and R. Latimer, propose to name the new element lawrencium in honour of the late Ernest Orlando Lawrence, inventor of the cyclotron and founder of the laboratory which bears his name. Californium, used as the target material, is made by the prolonged irradiation of trans-uranium elements in a nuclear reactor by the successive addition of neutrons. Since each new heavy element is more unstable than the one before, this procedure is inapplicable to the heaviest elements and heavy-ion bombardment is the only route whereby they may be created. In addition, the identification of the heaviest elements prepared in this way becomes progressively more difficult with increasing atomic number owing to their instability and to the very few atoms of the product which are formed. Although it may be possible to create one or two more new elements by this technique, it is improbable that elements beyond number 105 will be synthesized and satisfactorily identified.

Ministry of Aviation : Mr. J. R. Mills

Mr. J. R. Mills has been appointed head of the Radio Department, Royal Aircraft Establishment, Farnborough. Educated at the Grammar School, Kingston-on-Thames and King's College, London, he completed in 1939 the special honours course in physics. Shortly after war broke out Mr. Mills joined the Air Ministry Research Establishment, Dundee (formerly Bawdsey Research Station). It was here that he began his connexion with radar. Between 1940 and 1944 he divided his time between the Ministry of Aviation Radio Department, the Royal Aircraft Establishment and the Telecommunications Research Establishment, working throughout most of this period on the problems of secondary radar systems, mainly in the metric wave-bands. In 1946 Mr. Mills was a member of the team at the Telecommunications Research Establishment which had been set up to develop electronic systems for use in civil aviation, his particular interest lying in the development of distance measuring equipment. During this period his group was one of the first in the United Kingdom to investigate the use of overtone crystals as frequency sub-standards. In 1950 he returned to the military field and concentrated on techniques for measuring range to a very high order of accuracy. From 1952 he led a team set up in the Telecommunications Research Establishment to carry out research into new forms of airborne surveillance radar and, in particular, to exploit the new wave-band (Q) centred on a wave-length of 0·86 cm. During 1954–60 Mr. Mills was the superintendent in the Airborne Radar Department, Royal Radar Establishment (formerly Telecommunications Research Establishment and the Radar Research Development Establishment), in charge of research and development concerned with the offensive airborne operational needs of the Royal Air Force and Royal Navy. For a brief period commencing in October 1960 he was the assistant director at Ministry of Aviation Headquarters concerned specifically with the electronic problems of civil aviation.

Mr. J. H. Briggs

Mr. J. H. Briggs has been appointed director of electronics, research and development (civil aviation) in the Ministry of Aviation. Mr. Briggs was educated at King Edward's School, Birmingham, and obtained a major open scholarship in natural sciences at St. John's College, Cambridge, where in 1935 he graduated with honours in the Mathematical Tripos Part I and Natural Sciences Tripos Part II (physics). After a year and a half in the carrier communications development laboratory of the General Electric Co. he joined the Government service at the Royal Aircraft Establishment, where for three years in the Radio Department he was engaged on direction-finding research and development. On transfer to the Air Ministry Research Establishment at Swanage in 1940 initial work on radar aerial systems led to anti-surface vessel development and then to a period of liaison work with Coastal Command to investigate the utilization of anti-surface vessel Mk. 2 and prepare for the introduction of centimetre anti-surface vessel for the Battle of the Atlantic. On return to the Telecommunications Research Establishment at Malvern a period in charge of test-gear development was followed at the end of the War by the organization and running of a research programme on microwave measurements in conjunction with the Radio Research Station of the Department of Scientific and Industrial Research. During this period he was for a time chairman of the Inter-services Radio Measurement Committee (later the Radio Electronic Measurements Committee).

In 1950 Mr. Briggs undertook a programme of work involving simulation and computation to establish a mathematical model of a homing test vehicle for comparison with the results of flight trials. In 1955 he became a superintendent in the Ground Radar Department, Radar Research Establishment, in charge of the development of data handling systems, and as such was intimately concerned with the overall design of air defence systems. These interests resulted in participation in extensive negotiations within the Nato framework in connexion with the co-ordination of European defence requirements—particularly in the field of military data-processing and exchange. The recently renewed interest in co-ordination of defence and air traffic control requirements brought him into close touch with civil aviation problems so that he is particularly well qualified for his new appointment.

United Kingdom Atomic Energy Authority Appointments

The Atomic Energy Authority and the National Institute for Research in Nuclear Science have agreed that the development of particle accelerators hitherto carried out by the Accelerator Division, Atomic Energy Research Establishment, Harwell, should be the responsibility of the Rutherford Laboratory of the National Institute for Research in Nuclear Science. Mr. L. B. Mullett, the head of the Accelerator Division, has joined the Rutherford Laboratory as assistant director for accelerator and applied physics. Other appropriate staff transfers have already been made.

Consequent on the appointment of Dr. R. Spence as deputy director of the Atomic Energy Research Establishment, Harwell, Dr. W. Wild has been appointed head of the Chemistry Division. He has responsibility for the scientific work of three branches: Chemical Processing and Reactor Chemistry; Radiation Chemistry and Solid State Chemistry; Radiochemistry. Mr. A. A. Smales, head of the Analytical Chemistry Branch, has been given the status of a division head and will be directly responsible to the director of the Establishment for the scientific work under his control. His branch will continue to use the general administrative services of the Chemistry Division.

Day-release Students in England and Wales

In a written answer in the House of Commons on April 14, the Minister of Education, Sir David Eccles, gave the number of day-release students under 18 years of age enrolled in major establishments of further education in England and Wales in 1959–60 as 191,526 boys and 50,976 girls. Of these, 91,009 boys and 23,419 girls were in the English counties (including London), and 91,070 boys and 26,247 girls in the English boroughs; only 6,501 boys and 857 girls were in the Welsh counties, and 2,946 boys and 453 girls in the Welsh boroughs.

Educational Statistics for England and Wales

As a complement to the national statistics which appeared in his annual report, "Education in 1959", the Minister of Education has now issued a wide range of statistical material concerning local education authorities in England and Wales (Selected Statistics relating to Local Education Authorities in England and Wales, Educational Year 1958–1959. Pp. ii+25. (London: H.M. Stationery Office, 1960.) 3*s*. net). The booklet contains estimates of the total population of the two countries and statistics of the total number of scholars in primary and secondary schools, and in training colleges in counties and county boroughs in England and Wales. There is also interesting information about the number of medical officers, dental officers and nurses serving each local authority; the number of pupils receiving milk and school meals; the number of awards made by local authorities to students wishing to study at a university or elsewhere—the latter show that sufficient discrepancies occur to make implementation of the full recommendations of the Anderson Committee a matter of urgent necessity.

U.S. Project Mohole

The National Academy of Sciences and the National Science Foundation announced recently that the experimental drilling ship, *Cuss I*, operating in 12,000 ft. of water off the west coast of Mexico in the Project Mohole, obtained, for the first time, a sample of the so-called second layer under the softer sediments of the ocean floor. This layer, the presence of which has been previously known only by reflexions of seismic soundings, has been revealed as basalt. This hole, which was begun at Guadalupe Island on March 31, reached a depth of 490 ft. after 11 hr. of drilling. Coring then began, and cores of soft, grey-green clay of Miocene age were obtained to a depth of 560 ft. At that depth the drilling-rate abruptly decreased and when the core barrel was retrieved, it was found to contain a hard, fine-grained basalt; the drilling had achieved threshold to the sima.

Animals for Cancer Research

The provision of animals for cancer research was discussed at a symposium sponsored by the Laboratory Animals Centre of the Medical Research Council Laboratories on May 23, 1960. Discussion was mainly concerned with the desirability of providing suitable animals from a central organization or whether users should provide their own locally. The dilemma was posed by Prof. J. S. Mitchell, of the University of Cambridge, who acted as chairman of the symposium, and indicated that the provision of animals for research needs expert knowledge, including that of mammalian geneticists and veterinary experts. The problem is not only one of size but also involves many technical problems, including. for example, continued testing to make certain the strains are authentic, and maintenance of the production of disease-free animals. The great contribution to cancer research has been the development of inbred strains of animals, especially mice, and the use of $F1$ hybrids between two inbred strains. At the present time, about eighty inbred strains of mice are known. Much less seems to be known about the genetics of rats. There are a few, perhaps not more than five, pure strains of rats. It is questionable whether the maintenance of all these strains, that is, about eighty inbred strains of mice and perhaps five inbred strains of rats, is necessary for cancer research. Prof. Mitchell believes that there is need to establish a large organization with expert staff and proper financial support to provide animals and tumours needed for cancer research. A full report of the symposium has now been published by the Centre (Collected Papers, Vol. 9, 1960. Pp. 116. Carshalton, Surrey: Laboratory Animals Centre, Medical Research Council Laboratories, 12*s.* 6*d.*).

Paranormal Phenomena

ALTHOUGH almost all physiologists regard the brain as in some sense the 'organ of mind', it has to be admitted that our knowledge of its action is still distressingly incomplete. In his fourteenth Frederic W. H. Myers Memorial Lecture, Dr. W. Grey Walter provides a most useful survey of recent work on the neurophysiological aspects of hallucinations and illusory experience (*The Neurophysiological Aspects of Hallucinations and Illusory Experience.* Pp. 24. (London: Society for Psychical Research, 1, Adam and Eve Mews, W.8, 1960.) 2*s.* net). As he points out, it is now possible to evoke by experimental techniques a variety of bizarre subjective states long thought to be peculiar to epilepsy or kindred nervous disorder. These techniques include rhythmic photic stimulation, sensory deprivation and the use of psychotomimetic drugs; the results obtained go far to justify Dr. Grey Walter's hope that many phenomena formerly consigned to the occult may come to achieve reputable neurophysiological explanation. At the same time, he finds little to say about those aspects of hallucinations which particularly interested Myers, such as their occasional (though apparently well-authenticated) telepathic character. It would seem, then, that neurophysiology has still far to go before it can provide an acceptable explanation of paranormal phenomena.

The Raffles Museum, Singapore

The Bulletin of the Raffles Museum, Singapore (No. 26; February 1961), maintains the high standard of research results that is now associated with this well-known publication. All the papers deal either with zoological or palæontological subjects based on Malaya and are well and clearly illustrated. An interesting experiment relates to an attempt to hatch the eggs of the leathery turtle, and a brief account of the geology of the limestone hills of Malaya is an important contribution to the stratigraphy of the region.

Museums Association: Monthly Bulletin

AFTER publishing the *Museums Journal* each month for 60 years without a break it has now been decided to issue a monthly *Bulletin* and a quarterly *Journal.* The first issue of the former (No. 1, April 1961) has just appeared. It is a 4-page production giving essential and current museum news and notices, obituary notices, recent appointments, letters to the editor, a list of temporary exhibitions in certain museums and details of posts now vacant in museums and art galleries.

'Araldite' in Museum Work

Technical Notes, No. 218, issued by C.I.B.A. (A.R.L.), Ltd., gives some interesting examples of the use of 'Araldite' in the numerous problems confronting museum staffs ('Araldite' in Museum Work. Pp. 10. Duxford: C.I.B.A. (A.R.L.), Ltd.; February 1961). The resin can be used either to assemble broken and fragile articles or to reinforce and consolidate museum objects and thus preserve them for posterity. The examples quoted include the Kentmere boat unearthed in Westmorland during 1955 strengthened by the use of a formulation consisting of 'Araldite' *CY* 219 (50 parts), hardener *HY* 219 (25 parts), accelerator *DY* 219 (1 part) and dibutyl phthalate (10 parts). Other objects dealt with in a somewhat similar manner were a Nigerian ceremonial mask, the St. Ninian's hanging bowl dating from about A.D. 800, and a Belgic wrought-iron frame. Other museum objects quoted are from the Royal Scottish Museum, Edinburgh, where repair work with 'Araldite' has been carried out with success including colour matching if the glue line is rather wide.

Poultry Keeping

KEEPERS of fowls, ducks and geese will welcome the publication by the Ministry of Agriculture, Food and Fisheries of its two Bulletins on these birds. One of these, entitled *Poultry Breeding* (Bulletin No. 146. Third Edition. Pp. vi+146. By G. E. Mann. London: H.M.S.O., 1960. 7*s.* net), contains 146 pages of valuable information written by G. E. Mann, poultry advisory officer of the National Agricultural Advisory Service, on the genetics of poultry, the inheritance of breed and economic characteristics and on mating systems and systems of breeding, with a glossary explaining technical terms. One of its aims is to give the smaller breeder practical information about the methods used by the larger breeders. The other Bulletin, entitled *Ducks and Geese* (Bulletin No. 70. Pp. v+93+8 plates. Fourth Edition. London: H.M.S.O., 1960. 6*s.* net), will interest those who find that these birds are not only interesting in themselves, but also profitable either as a large-scale enterprise or as a side-line. Their rate of egg production and of food conversion is high, and this Bulletin takes the reader step by step through the intricacies of choosing a good breed, methods of breeding, management, rearing and fattening, and of the marketing of eggs and birds. There is also some information about by-products, and the diseases of ducks and geese and their prevention and control. Written by experienced contributors, this Bulletin provides sound, practical advice. It has five appendixes on nutrition, the preparation of the birds for the oven, feeding trials, losses of weight due to plucking and trussing ducklings and a summary of the main breeds and their characteristics. Its eight pages of excellent photographs include portraits of ten breeds and pictures of how to handle birds when they are being sexed. Its twelve line-illustrations are all also of practical value.

Test on Recording Spectrophotometers

THE Photoelectric Spectrometry Group is organizing a collaborative test on commercially available recording ultra-violet spectrophotometers which will be based, so far as possible, on the successful test on manually operated instruments that was reported in the *Photoelectric Spectrometry Group Bulletin*

No. 4 (1951). A pilot run to establish the conditions of the test has been successfully conducted on approximately 10 instruments of 5 different makes. It is hoped that as many separate examples of all commercially available instruments can be included in the full-scale test, which it is expected will be initiated in October of this year. Sample solutions will be supplied to those who agree to enter the test and they will be asked to run spectra (*a*) under predetermined instrumental conditions, (*b*) under their own preferred conditions. The analysis of the results of the test will be published in the *Bulletin*. Anyone who would like to enter a recording ultra-violet instrument should write to the honorary secretary, K. A. Macdonald, Unicam Instruments, Ltd., Arbury Works, Cambridge.

The Devon Naturalists Trust

A BODY, to be known as the Devon Naturalists Trust, has been formed with the support of many national and local bodies including the Nature Conservancy, the Council for Nature and the Devonshire Association. Lord Roborough is to be president of the Trust, and Mr. H. G. Hurrell chairman of its executive committee. The aims of the Trust are to protect places of interest to naturalists, to preserve the county's wild-life against encroachment, and to encourage the study of natural history. These aims should appeal to many who are concerned at the tide of change that has already much reduced the natural amenities of other counties, and is beginning to do so in Devon, too. It will be one of the main concerns of the Trust to see that developments of this sort are kept under constant review. There will be a meeting in Exeter to invite support and to publicize the Trust on May 16. Further information can be obtained from the honorary secretary, C. P. E. Grant, Chain House, Modbury, Ivybridge, Devon.

Grants for Field Work in Natural History

AT the suggestion of the Council for Nature, the Carnegie United Kingdom Trust has set aside a fund from whch it will make grants to approved societies for assistance with field work. These grants will be made on recommendations submitted by the Council for Nature, and will be contributions towards expenditure incurred in carrying out specific projects that give amateurs experience of field work in natural history under skilled direction. Approved expenditure is likely to include fees paid to experts for instruction and leadership, the incidental expenses of such people and the cost of essential equipment subject to certain conditions. Grants will not be available for the expenses incurred by members of the societies taking part in any scheme or for the general support of a society. Full particulars of the conditions for the award of grants can be obtained from the Council for Nature, 41 Queen's Gate, London, S.W.7.

Library of Recorded Animal Sounds

A LIBRARY of recorded animal sounds is being set up by the Committee for Biological Acoustics in collaboration with the British Institute of Recorded Sound, 38 Russell Square, London, W.C.1, in the archives of which the records will be stored. The records will be made on magnetic tape and recorded at a standard speed of 7½ in. per sec.; each record will contain a commentary giving physical and biological data in relation to the recording. The recordings will be available free on loan to bona fide research workers anywhere in the world and the only expenses will be postage of the tapes. The library is being supported by a grant for equipment from the Royal Society. As soon as a reasonable number of recordings have been amassed a catalogue will be prepared and sent free of charge to all interested workers, departments and institutions. It is hoped that all workers in the field will give their support to the project, and those willing to allow their recordings to be copied for the library are asked to write to Dr. P. T. Haskell, Committee for Biological Acoustics, c/o Anti-Locust Research Centre, 1, Princes Gate, Kensington, London, S.W.7.

Japan Association for Study of Congenital Anomalies

THE Japan Association for Study of Congenital Anomalies held its initial meeting at the Kyoto University, Faculty of Medicine, on February 25, 1961. For the time being, the Association has been established on an informal basis, by an organizing group consisting of the following members: Prof. Chisato Araki (Kyoto University); Prof. Tameyoshi Baba (Osaka Municipal University); Prof. Ichiro Hayashi (Nagasaki University); Prof. Yoshiki Mikami (Mie Prefectural University); Shigeru Mitani (Tokyo Women's Medical College); Prof. Ujihiro Murakami (Nagoya University); Prof. Hideo Nishimura (Kyoto University). Prof. Nishimura and a member of the organizing group will be in charge of international affairs.

Association of Consulting Scientists

AT the annual general meeting of the Association of Consulting Scientists, held in London recently, the following honorary officers and members of council were elected: *chairman*, Dr. M. Barent (Barent and Johnson); *vice-chairman*, Mr. F. G. Sarel Whitfield (Avebury Research Laboratories, Ltd.); *honorary treasurer*, Dr. G. W. Ferguson (Parry and Ferguson); *honorary secretary*, Mr. W. H. Stevens (W. H. Stevens); *members of council*, Dr. H. H. Chambers (Sondes Place Research Laboratories, Ltd.), Dr. J. G. Davis (Dr. J. G. Davis and Partners), Dr. Julius Grant (Hehner and Cox, Ltd.), Dr. R. F. Milton (R. F. Milton), Mr. O. W. Roskill (O. W. Roskill).

1961 Waverley Gold Medal Essay Competition

THE Waverley Gold Medal essay competition is sponsored by *Research* to encourage scientists to write clearly and comprehensibly about their work. The Medal, together with £100, will be awarded for the best essay of about 3,000 words describing a new project or practical development in pure or applied science, giving an outline of the scientific background, the experimental basis and the potential or actual application of the idea to industry or its importance to society. A second prize of £50 will be awarded and also a special prize of £50 for the best entry from a competitor under the age of thirty on July 31. Entry forms and further information can be obtained from the Editor of *Research*, 88 Kingsway, London, W.C.2. The last date of entry is July 31.

Film-Strips on Physical Science

A CLASSIFIED list of their film-strips and wall-charts in physics, chemistry and general science has been issued by Educational Productions, Ltd., of East Ardsley, Wakefield, Yorks. The strips deal with such topics as the structure of matter, electricity and light, while there is also a whole series of wall-charts linked to the products of prominent industrial organizations and produced in collaboration with them. Wall charts are also available to describe lessons in astronomy and space exploration.

Guide to Careers

As a link with the Commonwealth Technical Training Week which is to be held during May 29–June 4, the 1961 edition of the *Guide to Careers* published by the National Union of Teachers is mainly concerned with the training of young people in industry and commerce (Pp. viii+80. London: National Union of Teachers. 1961). In a foreword to the Guide, H.R.H. the Duke of Edinburgh directs attention to the need for careful choosing of careers. Many experts describe the different careers available to young people, and these are supported by even more advertisements in which the advantages of a particular company or organization are displayed. School-leavers themselves are likely to find the mass of generalizations somewhat overwhelming, and will seek refuge in the related experiences of some young people who have already tried out certain jobs for themselves. Even these tend to be over-glamorized and should be balanced by descriptions from young people with experience of jobs somewhat more mundane than that of staff manageress or management trainee.

Postgraduate Courses in London

PARTICULARS of full-time postgraduate courses of one or two years duration which lead to a degree or diploma are contained in a booklet *Postgraduate Courses*, 1961–62, issued by the Imperial College of Science and Technology (Pp. xii+114. London: Imperial College of Science and Technology, 1961). These courses, which have been accepted by the Department of Scientific and Industrial Research as suitable for the tenure of advanced course studentships, are indicated, and besides outlining the content of the individual courses, their length and the respective lecturers, the booklet includes the regulations for the diploma of the Imperial College of Science and Technology.

Gordon Research Conferences 1961

THE Gordon Research Conferences have justly achieved international fame as effective instruments for the exchange of ideas and information between research scientists drawn from industrial, Government and academic laboratories, and the organizers have been paid the great compliment of having their methods copied in other countries. Papers are presented at morning and evening sessions over a period of four and a half days and the formal programme is often very slight, for example, in the 1961 Petroleum Conference only six papers are scheduled for formal presentation. There is ample time for discussion, the environmental and residence conditions are all favourable and the selected membership ensures that the discussion is free and of a high level. As in previous years a conference will be held each week during June 12–September 1 at each of three residential schools in New Hampshire, and the subjects cover a wide range in the physical and biological sciences. Residence and registration charges for a week amount to 100 dollars. Further information can be obtained from Dr. W. George Parks, Department of Chemistry, University of Rhode Island, Kingston, R.I. Applications for attendance should be submitted before June 12.

University News:

Bristol

THE following appointments to senior lectureships have recently been announced: Mr. R. Bassindale (zoology); Dr. A. Couper (inorganic and physical chemistry); Dr. F. G. Hannell (geography); Dr. J. R. Holmes (veterinary medicine); Dr. W. K. Metcalf (anatomy); Mr. W. H. Dearden (metallurgy); Dr. M. S. G. Cullimore (civil engineering).

Cambridge

THE Arnold Gerstenberg studentship for 1962 is open to students in the University of Cambridge who, going into residence not earlier than 1956, have obtained honours in the Natural Sciences Tripos and who wish to pursue a course of philosophical study. The studentship will be awarded for an essay, which must be submitted before May 1, 1962. Further information can be obtained from Mr. Gerd Buchdahl, Whipple Science Museum, Free School Lane, Cambridge.

London

THE following announcement has been issued by the Imperial College of Science and Technology: Prof. D. M. Newitt, pro-rector and head of the Department of Chemical Engineering and Chemical Technology, who retires on September 30, has been appointed senior Research Fellow of the College. Prof. P. M. S. Blackett has been appointed pro-rector as from October 1, and Prof. A. R. Ubbelohde as head of the Department of Chemical Engineering and Chemical Technology. The following have been elected Fellows of the College: Prof. O. M. B. Bulman, Woodwardian professor of geology, University of Cambridge; Prof. A. C. Chibnall, professor emeritus, former professor of biochemistry; Mr. T. G. N. Haldane, member of the Governing Body of the College; Dr. D. T. A. Townend, director-general of the British Coal Utilization Research Association; Dr. J. H. Watson, chief assayer, Royal Mint.

Dr. A. H. Chilver, a director of studies in engineering, University of Cambridge, has been appointed to the Chadwick chair of civil engineering tenable at University College. Dr. F. G. Bailey, lecturer in Asian anthropology at the School of Oriental and African Studies, has been appointed to the University readership in Asian anthropology tenable at that School. Dr. E. G. Gray, lecturer at University College, has been appointed to the University readership in cytology tenable at that College.

Titles have been conferred as follows: Sir William Collins professorships, on Mr. G. W. Causey (anatomy) and Dr. G. J. Cunningham (pathology) in respect of the posts held by them at the Institute of Basic Medical Sciences; reader in veterinary physiology at the Royal Veterinary College, on Dr. F. R. Bell; reader in anatomy at St. Mary's Hospital Medical School, on Dr. A. S. Breathnach; reader in physics at University College, on Dr. F. F. Heymann; reader in chemistry at University College, on Dr. J. Lewis; reader in chemical engineering at University College, on Dr. J. W. Mullin.

Sheffield

THE title of Dr. G. Weber's readership has been announced as reader in biophysics. J. E. Enderby has been appointed as a lecturer in physics; and Dr. J. V. S. Mani has been appointed an Imperial Chemical Industries research fellow in the Department of Fuel Technology and Chemical Engineering.

Southampton

THE origins of the University of Southampton lie within the Hartley Institute, established from a bequest by H. R. Hartley in 1862. Towards the University's centenary appeal, Hawker-Siddeley Aviation, Ltd., is contributing a sum of £28,700, over a period of seven years, for a readership and a lectureship in the Department of Aeronautics and Astronautics; Alcan Industries, Ltd., is contributing a sum of £10,000.

The title of senior lecturer has been conferred on Mr. K. N. C. Bray (aeronautics and astronautics), Dr. W. A. Gambling (electronics), Dr. N. S. Grassam (mechanical engineering) and Dr. A. C. Riddiford (chemistry). The following new appointments have been made: Mr. V. J. D. Baston, Dr. H. Holstein and Mr. C. R. F. Maunder (lecturer in mathematics); Mr. W. S. Hall and Mr. T. Sprinks (Research Fellows in mathematics); and Mr. G. C. Spencer (lecturer in mechanical engineering).

Announcements

SIR HAROLD ROXBEE COX, formerly chief scientist of the Ministry of Fuel and Power and at present chairman of the Metal Box Co., Ltd., has been appointed chairman of the Council for Scientific and Industrial Research for five years from October 1, 1961, in succession to Sir Harry Jephcott, who completes his term of office in September.

MISS M. J. BISHOP, headmistress of the Godolphin and Latymer School, Hammersmith, has been appointed a member of the University Grants Committee in succession to Dame Kitty Anderson, who resigned from the Committee on her appointment as a member of the Committee on Higher Education. Miss Bishop's appointment runs to December 31, 1963.

THE United Nations Food and Agriculture Organization is organizing a technical meeting on "Plant Exploration and Introduction", to be held in Rome during July 10–20. Further information can be obtained from the Food and Agriculture Organization, Viale delle Terme di Caracalla, Rome.

A TECHNICAL meeting of the United Nations Food and Agriculture Organization to discuss "Plant Exploration and Introduction" is to be held during July 10–20, at the headquarters of the Organization in Rome, from which further information can be obtained.

THE summer conference of the Society for Applied Bacteriology will be held at Wye College, Kent, during July 11–13. Included in the programme is a symposium on "Bacteria of the Intestine". The conference is open to all, and further information can be obtained from Dr. Ella M. Barnes, Low Temperature Research Station, Downing Street, Cambridge.

THE second congress of the International Federation of Societies of Cosmetic Chemists, organized by the Society of Cosmetic Chemists of Great Britain, will take place in London during July 2–5. Further information can be obtained from A. Herzka, c/o Pressurized Packaging Consultants, Ltd., Ashbourne House, Alberon Gardens, London, N.W.11.

THE sixty-sixth annual congress of the South-Eastern Union of Scientific Societies will be held at Haslemere, Surrey, during May 26–28. The theme of the congress will be "The Changing Country-side" and the programme will include a number of lectures, a brains trust and various excursions. Further information can be obtained from the general secretary and treasurer, Frank Edwards, 53 The Drive, Shoreham-by-Sea, Sussex.

THE eighth International Cancer Congress will be held in Moscow during July 22–28, 1962, under the auspices of the International Union against Cancer. The Congress will meet at the Moscow State University and will consider both experimental and clinical aspects of the problem. Further information can be obtained from the general secretary of the Soviet National Organizing Committee, Prof. L. Shabad, or the assistant general secretary, Dr. N. Perevodchickova, Academy of Medical Sciences of the U.S.S.R., 14 Solyanka, Moscow.

AN international exhibition, devoted to measurement control, regulation and automation, is being held in Paris during May 9–17. The exhibition is being organized by the MESUCORA Association in conjunction with the Fédération des Industries Mécaniques et Transformatrices des Métaux, the Syndicat Général de la Construction Electrique, and the Fédération des Industries Electroniques. This event will also include the annual exhibition of the Société Française de Physique. Further information can be obtained from Congress International, MESUCORA, 40 Rue du Colisée, Paris, France.

HATFIELD TECHNICAL COLLEGE is organizing a series of lectures on the general theme "Technology, Science and Art—Common Ground". The details are as follows: "Science in History" by Prof. J. D. Bernal (May 5); "Poetry and Science" by T. R. Henn (May 12); "Science and Ethics" by Dame Kathleen Lonsdale (May 26); "Science and the Classics" by Prof. B. Farrington (June 2); "Art and Engineering" by Prof. M. Black (June 23). All lectures will be held in the Old Library of the College on the dates indicated. Further information can be obtained from Mr. I. O. McLuckie, chairman, Teaching Staff Association, Hatfield College of Technology, Hatfield, Herts.

THE 1961 Conference on Medical Electronics, which is to be held at the Waldorf Astoria Hotel, Park Avenue and 49th Street, New York City, N.Y., during July 16–21, will be a combined meeting of the fourth International Conference on Medical Electronics and the fourteenth Annual Conference on Electrical Techniques in Medicine and Biology. It is to be sponsored by the Joint Executive Committee on Medicine and Biology under the auspices of the International Federation for Medical Electronics, and is organized by the Institute of Radio Engineers. Further information can be obtained from the Secretary-General, Fourth International Conference on Medical Electronics, Institute of Radio Engineers, 1 East 79th Street, New York 21, N.Y.

A COURSE in tropical hygiene for laymen will be held by the Ross Institute during July 3–7. The course is designed specially for planters, mining engineers and other non-medical people who may be responsible for the health of industrial labour forces in the tropics. Admission is not restricted to such people, however, but is open to any non-medical men and women proceeding to the tropics. Further information can be obtained from L. G. Ponsford, organizing secretary, Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, Keppel Street (Gower Street), London, W.C.1.

MALNUTRITION

ON March 18, the Nutrition Society held, at the London School of Hygiene and Tropical Medicine, a symposium on "The Place of Food Science and Technology in the Campaign against Malnutrition". The symposium was primarily concerned with malnutrition in the under-developed countries, and in particular with malnutrition in children in the 'toddler' stage.

There is much evidence that malnutrition associated with lack of protein and calories is common in countries in which supplies of foods of animal origin, especially animal milk, are low; it is, in fact, the most common of all food deficiency states in the world as a whole. Its manifestations range from retardation in growth to serious disease and death. The West African word 'kwashiorkor' is now widely used to describe a form of the disease, with characteristic signs, occurring in children whose diet is grossly deficient in protein and less deficient in calories. The wider term 'protein–calorie malnutrition', covering the effects of both lack of calories and lack of protein, usually found together in the victims, is preferred by many workers, but it should be added that at present there is some confusion with respect to nomenclature.

As the result of intensive research during the past ten years in many parts of the world, the factors underlying protein–calorie malnutrition—dietary, agronomic, economic and social—are now well understood, but relatively little progress has as yet been made in prevention. Through food science—meaning in this context the study of foods and food values in relation to requirements—appropriate measures for correcting deficiencies can be demonstrated, and food technology, wisely applied, can increase supplies of nutritious foods pending, and in association with, the expansion of food production.

The symposium began with five papers, under the heading of "Problems and Some Solutions", given by workers from India (Dr. K. K. Halder), Turkey (Dr. O. Köksal), Iraq (W. Frankul), Pakistan (S. M. Ali) and Ghana (R. Orra ca-Tetteh) respectively, who are engaged in research at the Human Nutrition Research Unit at Mill Hill, under the direction of Prof. B. S. Platt. Each speaker outlined the background of the problem in his country and described some locally feasible method or methods, based on recent research, of making diets more satisfactory. These papers brought out on one hand the basic similarity of the situation in various parts of the world, and on the other, the differences from country to country which call for a local approach in applying food science and technology effectively. In introducing these contributions, Prof. Platt commented on the value of providing postgraduate experience in nutrition research and its application to workers from countries in which there are serious problems of nutrition and a shortage of trained personnel to deal with them.

A paper on "Some African Problems" by Dr. F. Aylward (Department of Chemistry and Food Technology, Borough Polytechnic, London) reflected the author's experience as adviser to the Ministry of Agriculture in Ghana in the capacity of a technical assistance expert for the Food and Agriculture Organization. He analysed the contributions which food technology can make in increasing supplies of nutritious foods available for consumption, suggesting various categories into which these contributions can be grouped. His paper was concerned with the application of food technology in ways which do not demand big capital outlay, rather than with the development of large-scale food industry. He considered that under African conditions there is an important place for small food-processing plants in rural areas, with low maintenance costs and minimum requirements for technical supervision. Dr. J. W. Corran (J. and J. Colman, Ltd., Carrow Works, Norwich), who dealt with "Factors Affecting Development of Food Science and Technology and Food Resources in Pakistan", also drew on experience gained during a Food and Agriculture Organization assignment as a technical assistance expert. He directed attention to the lack of accurate data about food consumption and state of nutrition and of reliable agricultural statistics, which handicapped attempts to formulate and execute programmes to develop food production and food technology. For example, there were widely conflicting estimates of supplies of fish, an important food in East Pakistan. While Pakistan greatly needed trained food scientists and technologists, the number of active workers in these fields could at present be counted on the fingers of one hand. Facilities for training such workers in Pakistan did not exist, and even those available in the United Kingdom were far from satisfactory. Pakistan urgently needed the help of food technologists from abroad to foster the growth of food industry.

Dr. E. Wokes (Vegetarian Nutritional Research Centre, Research Laboratory, Stanborough School, Watford, Herts) discussed "India's Food Problems" on the premise that substantial increase in supplies of animal protein could not be expected in the foreseeable future. Attention must therefore be focused on plant proteins, which are cheaper than animal proteins, and may be obtained from pulses, groundnut preparations, leaf protein concentrates, and other sources. The lack of vitamin B_{12} in plant proteins might be corrected by fortification with the synthetic vitamin itself. He referred to deficiencies of lysine and methionine in average Indian diets and to possibilities of making these good by suitable combinations of vegetable foods. In conclusion, he stressed the need for more clinical and nutritional research, and for developments in food technology, food control, agriculture, transport and education.

An account was given by Dr. W. F. J. Cuthbertson (Glaxo Laboratories, Ltd., Greenford, Middlesex) of "The Commercial Development of 'Amama', a protein-rich Supplement in Nigeria". This preparation, based on groundnut flour to which casein, yeast, minerals and vitamins are added, is manufactured in a factory near Lagos. Tests made in Nigeria, where protein malnutrition is common, showed that 'Amama' was as effective in treating malnourished children as skim milk powder. Cuthbertson emphasized that the manufacture and distribution of a new food to wholesalers and retailers were not enough to ensure its use; an advertising and educational programme was essential so that the public can become aware of its availability and how to use it. He outlined the methods followed in promoting the sale of 'Amama', and the difficulties encountered.

Throughout the symposium there were many references to the need for popular education in nutrition, which must accompany all other measures to eliminate malnutrition. The last paper, by Dr. A. T. M. Wilson (Unilever House, Blackfriars, London), on "Nutritional Change; Some Comments from Social Research", dealt mainly with this subject. He quoted effectively a passage in a World Health Organization report about the "baffling maze of tradition, taboo and magic, and the whole system of belief of the people about health and the causes of disease" of which educators must be aware. "In the past", the World Health Organization report continued, "most workers have tried, by repeated blows of didactic teaching, to hammer their way through the maze and break down the resistance to unaccustomed foods and eating practices—with very little success . . . because beliefs about food are part of the whole fabric of the life of a people". It follows that the social and psychological aspects of the campaign against malnutrition are of essential importance, an example being the complex social factors which influence lactation and weaning. Wilson also commented that the campaign called for co-operation between different disciplines and services, always difficult to secure. The epigram "God has not seen fit to divide our problems into the same categories as university chairs" was highly applicable to the problem of nutrition.

The papers and discussions at the symposium gave at least some answers to the questions implied in its title. While the general attitude was optimistic, the speakers recognized that immediate and facile solutions cannot be expected. There was emphasis on the need for action based on research and on an understanding of the complex factors which cause malnutrition.

W. R. AYKROYD

GROWTH AND GENETICS OF HIGHER FUNGI

THE higher fungi commonly known as mushrooms, toadstools and bracket fungi and classified in the Basidiomycetes, have certain distinctive biological features which make them a favourable group in which to study their physiology of growth and their genetics. The large fruiting body with its size, shape and form, and in many species with its extraordinary rate of growth, offers opportunities for studying the factors affecting growth, translocation and morphogenesis. The mycelium with its regular growth-pattern, its production of asexual spores and its ability to grow on simple minimal medium has all the properties of mycelia in other groups of lower fungi. The regular formation of a stable dikaryon from the compatible mating of monokaryons provides a system for studying gene action which is intermediate between the regular haploid–diploid cycle of yeast and the variable heterokaryon and homokaryon in *Neurospora* and *Aspergillus*. The complex mating system in the higher fungi, although it can be compared in its genetics with certain incompatibility systems in higher plants, has features that are not found in any other group of plants.

In a symposium organized by the British Mycological Society, under the chairmanship of its president, Miss G. M. Waterhouse, five aspects of the higher fungi were examined: (1) the effects of light and gravity on the growth and form of a fruiting body; (2) the factors, both internal and external to the hyphæ, which govern the regular pattern of growth and branching of the mycelium; (3) the extent of gene action and the transport of exogenous substances along the hyphæ; (4) the genetic and possible biochemical control of the complex mating system; (5) the mosaic structure of populations and sterility barriers in higher fungi.

Dr. B. E. Plunkett (Birkbeck College, London), using the fruiting-bodies of *Polyporus brumalis*, demonstrated components of the complex system of stimuli that operate to keep the cap horizontal and to ensure the production of spores on the lower side. These are factors of importance if the fungus is to distribute its spores efficiently. The stalk of the young fruiting body, before the cap has expanded, grows towards a laterally placed light, but as the cap expands it is no longer attracted to the light but grows upwards under the influence of gravity on the horizontal stem. Light of low intensity obtained by shading the young stem with an artificial cap resulted in upward growth due to gravity. This showed that the geotropic response was present in the early as well as in the later stages of development. The weaker geotropic response is at first overruled by the strong photo-response, but later, as the perceptive region is shaded by the expanding cap, the geotropic response expresses itself. Rotation-with-light experiments demonstrated that the spore-bearing region develops away from the light and the cap develops at right angles to the incident light. These interesting studies in growth and morphogenesis were paraphrased by the statement that according to Corner the cap was an umbrella to keep rain from the spores, but now it could also be a parasol.

Turning from the fruit body to the mycelium, Dr. G. M. Butler (Birmingham) discussed the problems of the hyphal branching system in *Coprinus disseminatus*. Three types of hyphæ could be distinguished, main, primary branch and secondary branch. In Petri dish cultures the main hyphæ had the highest extension-rate and the greatest diameter, the secondary branch had the lowest rate and diameter. The monopoidal branching system and the radial growth of a colony depend on these differential extension-rates of leading and branch hyphæ. A steady rate of growth of a whole branch system is maintained, from which it is concluded that the hyphal tip, the region where extension occurs, is not autonomous but is subject to competition and interaction occurring within the hyphal system. Experiments with two cultures separated by 'Cellophane' and growing out of step showed that under certain conditions there existed hyphal competition or inhibition transmitted in the culture media, but this external effect, even at its greatest intensity, was too small to account for the difference between the main and branch hyphæ in extension-rate and diameter. Little is known about the main control of hyphal growth, which is internal, either in its extent along the hyphæ or in its mode of action, but it appears to operate on cell extension rather than on nuclear division.

Prof. D. Lewis (University College, London) discussed the problem of hyphal tip autonomy from a genetical approach and came to the same conclusion that the tip is not autonomous. A methionine-requiring mutant *me*-1 of *Coprinus lagopus* produced prototrophs not requiring methionine at a frequency of 2 in 10^5 asexual spores. These asexual spores are uninucleate and are cut off from the tips of hyphæ. The prototrophs are the result of recessive mutants of suppressor genes. Monokaryotic mycelia of the *me*-1 stock, when transplanted to minimal media, do not produce prototrophic sectors of growth despite the fact that hyphæ grow for 1 mm. into the minimal medium. The recessive mutant therefore is not expressed in the articulated hyphæ but is expressed in the isolated spore.

A dikaryon which is homogenic for *me*-1 and heterogenic for a suppressor gene will not grow on minimal medium, but each hypha resolves into a monokaryon with the nucleus carrying the suppressor gene. This difference between the monokaryon and dikaryon indicates that the sphere of gene action extends well beyond its own cell in a monokaryon, but in a dikaryon the same gene has a limited field of action and may be limited to its own cell. Experiments on the transport of exogenously supplied methionine in monocaryons and dicaryons did not reveal any difference between the two types of mycelia. Transport was limited to 1–3 mm. in both; this is a fact which may have a direct explanation for the lack of fruiting ability of many biochemical mutants when homogenic.

The unique mating system in the higher Basidiomycetes is controlled by two genetic loci *A* and *B*; one gene controls the migration of the donor nucleus in the receptor hyphæ and the other gene controls the regular synchronous division of the two nuclei and the formation of the clamp connexions which are peculiar to the Basidiomycetes. The *A* and *B* loci in *Schizophyllum commune* have been analysed into two genes in each.

Dr. P. R. Day (John Innes Institute) described a genetical analysis of the *A* complex in *Coprinus lagopus*. Using two auxotrophic mutants linked on both sides of the *A* locus, recombinants of the outside auxotrophic mutants were selected on minimal medium, and among these were a few *A* alleles which were different from the two parental alleles. The frequency of recombination to give these new alleles was 0·07 per cent. The recombining parts have been called sub-units; but whether these sub-units can be considered as two different functional genes or as different sites of the same functional gene cannot be decided. The frequency of 0·07 per cent is a value which is consistent with either alternative, and the important functional complementation test is not possible with this *A* locus in the present lack of knowledge of its action. But if the *A* locus is similar in *Coprinus* and in *Schizophyllum* which has two genes 4–10 per cent units apart, then two genes are indicated. It may be significant for the working of the incompatibility system that in all four species of higher fungi where recombination within the *A* and *B* loci has been tested on a sufficient scale, two sub-units or genes have been found.

Mutations affecting the *A* function were obtained in heterokaryons which had a common *A* allele. These were either changes at the *A* locus itself or at a gene suppressing the *A* function. All the mutants appeared to result in loss of function because monokaryons with these mutations produced spontaneously the clamps which are normally confined to dikaryons. A further analysis of the *A* locus using recombination and mutation should reveal further important details about its structure and function.

Prof. R. A. Raper (Harvard), who has been mainly responsible for the detailed analysis of the *A* and *B* loci in *Schizophyllum commune*, in his paper "An Enquiring Look at Tetrapolar Incompatibility", gave a penetrating and exhaustive review of the possible control systems which could be accommodated into the known facts about the *A*–*B* mating system in higher Basidiomycetes. Such a control system has to account for the high degree of specificity, and at the same time the great variation in the specific control. It also must be consistent with the genetic system, but as was pointed out, such a genetic system would have been subjected to exceptional selective pressures because of the unusual nature of the system, and it is possible that exceptional or even unknown gene action and interaction may be revealed by the system.

Three basic modes of biochemical control were considered: (1) an inhibitor system which is produced by like alleles to cause incompatibility; (2) an inhibitor which is present in the monokaryon, but which is removed by unlike *A* and *B* alleles to give a compatible dikaryon; (3) a complementary action between unlike alleles to elaborate an essential substance for the compatible dikaryon to become established. With our present knowledge of gene structure, function, interaction and complementation there are some difficulties with all three schemes, but Prof. Raper hoped that a solution might be forthcoming from a serological analysis which had already given promising results.

Prof. J. H. Burnett (Newcastle) described his results of surveying natural populations of several species of higher Basidiomycetes for their mating type *A* and *B* alleles. The survey included bipolar and tetrapolar species. The number of different alleles was large, but varied significantly between different groups. The genus *Nidularia* stands out from the rest by having a small number of alleles.

Fruit bodies sampled from the same tree and from the same clump revealed that different dikaryons were mixed together in a mosaic. Several examples of contiguous fruiting bodies were found to be genetically isolated from one another as shown by the failure of their spore colonies to mate. Mosaic cultures were reconstructed in artificial conditions, and it was concluded that the mycelium is not often a single ecological unit but a genetical mosaic.

The mosaic nature of the mycelium, together with the genetic sterility barriers between the components of a mosaic, may have its causative connexion. Genetically isolated components could only form a mosaic, but components not so isolated could fuse to give a dominant single dikaryon. But, like many aspects of higher fungi, whether this frequent isolation barrier has its cause in the unique mating system is not known.

BARLEY AND BREWING

THE European Brewery Convention belongs wholly to the post-war period and, in retrospect, it is surprising that, prior to its inception, no organization existed for the regular international exchange of scientific information and experience in relation to malting and brewing. There were of course various journals of high repute, but the differences in standards, industrial methods and laboratory procedures from country to country were not widely appreciated. Consequently, valuable though many published investigations were, they tended more to describe particular experience than verifiable fact. With the present volume in mind*, it can be still more clearly seen that the selection of barleys and of malting methods even in a single country could scarcely have been done scientifically so long as the lack of properly documented experience made it impossible to co-ordinate the economic and material requirements of the farmer, maltster and brewer.

The tenth annual report reveals that these earlier deficiencies have been largely remedied by a degree of integration in international investigation never before achieved in this connexion. For example, it gives, mostly in tabular form, the results of trial comparative cultivations, often with relevant malting and brewing trials, of some 12 new varieties of barley the majority of which were grown under highly controlled conditions in 14 western European countries. The data extend far beyond the expected facts on such matters as yield, nitrogen-content, dormancy, grind characteristics of the malts and head retention of the final beers making up the series of part-reports, each under separate authorship. Thus they include numerous details of the lay-out of each trial, the nature of its location, agricultural conditions, field observations and meteorological data. The report is therefore a reference work rather than a book to be read cursorily. There can be no doubt that it reflects what is, in its way, an exceptionally important step to find improved varieties of what is the basic raw material of an unusually widespread industry.

It may seem strange to some that this effort is so disseminated when much of the work could apparently be carried out centrally. Actually, however, this type of inquiry is unexpectedly complicated because it involves comparison not only of barleys as such but also of the conditions under which they are grown and processed. Broadly, therefore, the question arises as to whether the differences between varieties can outweigh the differences arising from varying methods of treatment, for example, of malting method. The European Brewery Convention Barley Committee is in an unrivalled position to sponsor investigations of this kind, and its report has therefore a scientific value beyond that of a factual record of a unique but continuing international exercise.

ADMISSION TO UNIVERSITIES IN BRITAIN

THE third report of an *ad hoc* Committee on Procedure for Admission of Students to Universities, appointed by the Committee of Vice-Chancellors and Principals of Universities of the United Kingdom in January 1958, has now become available*. The Committee was set up to consider what steps need to be taken to reduce difficulties experienced by candidates for admission and by the schools. The report contains the findings of a working party established under the chairmanship of Dr. A. W. Chapman to report on the methods and techniques by which the multiplication of applications for admission and the consideration of candidates could be reduced, the kind of central organization involved and any changes of principle as regards relations between universities and candidate. The Committee has been forced to conclude that the time has come when universities must consider the establishment of a central organization and a central office in connexion with applications for admission, and it was this conclusion which led to the establishment of the working party. Further, having been satisfied as to the technical feasibility of such central arrangements, the committee also concluded that it must now make recommendations which would cause the universities as a matter of urgency to consider the rapid establishment of co-operative arrangements, and this is the whole burden of the report.

The working party quickly recognized that it would be essential to have some kind of central office with information about every candidate and every institution, but equally that a candidate must have liberty to apply to a reasonable number of institutions of his own choice, and that the choosing of their students must remain entirely a matter for the universities.

Three schemes were submitted by the working party for consideration by the *ad hoc* Committee. One scheme looks to the maintenance of the present system, and the central office would only act as an information centre, as a means of checking candidates stated priorities and acceptances of places, and, in so far as time permitted, as a clearing house. Acceptance of this scheme is not recommended.

The other two schemes provide for a central office, equipped with data-processing machines, to which each candidate would make his or her application, naming a limited, but reasonably generous, number of institutions, to which he or she wishes to apply. It would be the duty of the central office to distribute the applications to the institutions concerned, to act as the channel through which all offers, whether firm or provisional, or rejections are conveyed to the candidate, to ensure that no other application remains in force once a candidate has accepted a firm offer, to provide a general clearing-up service operating from the earliest possible date in the admissions season, and to make full information to those who need it. Under the scheme preferred by the *ad hoc* Committee, though both are recommended to the consideration of the Committee of Vice-Chancellors and Principals, a candidate's applications would be released two or three at a time in an order chosen and specified by the candidate and a second pair of applications would ordinarily be released only after the results of the first pair had proved unacceptable. It provides that the selector must make a definite decision on an application within a given time-limit and can no longer wait until after his or her General Certificate of Education results before reaching a decision. Either scheme could be made effective for the intake of October 1964 if immediate steps were taken, and the Committee recommends the convening of a conference of representatives of the universities to consider the two recommended schemes and their application to the needs of the individual institutions.

---

* Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom. Third Report of an *ad hoc* Committee on Procedure for Admission of Students. Pp. v+41. (London: Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom, 1961.) 2*s*. 6*d*.

Neither scheme need adversely affect the direct relation between candidate and institution. In the light of the discussion at the conference, the Committee of Vice-Chancellors and Principals would invite universities to agree to establish a standing advisory council, and to authorize the necessary steps to establish a central office, including a small executive committee which would act as its governing body and control its policy and operation. These proposals and recommendations are limited to universities in England and Wales other than Oxford and Cambridge, but it is hoped that the colleges of Oxford and Cambridge will also consider entering the scheme and that, even if they do not enter fully, they will at least arrange to complete their selections for admission by the end of December or not later than mid-January. The proposals also seem to be applicable without difficulty to the Scottish universities.

Figures appended to the report show that for the institutions covered 151,000 applications were lodged for 1960–61, against 134,000 for 1959–60, 121,000 for 1958–59 and 70,000 for 1955–56, and in all 22,650 students were admitted to first degree courses in October 1960, compared with 20,300 in October 1959. Of the applications, 14,000 were from overseas candidates. Except for technological courses, the number of applications increased substantially compared with the previous year, though the number admitted to such courses increased by about 12 per cent. There is a notable decrease in the number of vacant places, except in technology, and there seems to be no doubt that, at present, too few adequately qualified candidates are applying for courses in the technologies and especially in the classical engineering subjects. It would appear that the clearing-up houses, established in the summer of 1960, as recommended in the *ad hoc* Committee's second report, have already contributed to the decrease in the number of vacant places.

CÆSIUM-137 IN AIR, PRECIPITATION, DRINKING-WATER, MILK AND BEEF IN NORWAY DURING 1959 AND 1960

By T. HVINDEN and A. LILLEGRAVEN

Division of Physics, Norwegian Defence Research Establishment, Kjeller

CÆSIUM-137 in air, precipitation and milk has been regularly measured at Bergen, Røros and Lillestrøm. The results for January 1959–December 1960 are shown in Fig. 1 as mean values over periods of two months.

Cæsium-137 in beef-samples from the same districts has also been measured. Cæsium-137 in drinking-water has been regularly measured at several places.

The Bergen district is a mountainous coastal area, Røros district is a mountainous inland area and Lillestrøm district is a lowland, inland area. The locations are shown on the map in Fig. 1.

As shown in Fig. 1*B* the concentration of cæsium-137 in ground-level air is at nearly the same level at the three measuring sites, and the variations occur simultaneously. There is one maximum during May–June 1959 and another, but much lower, in May–June 1960. The yearly average values are:

District	1959	1960	
Bergen	0·020	0·0042	$\mu\mu$c. cæsium-137/m.^{3}
Røros	0·019	0·0045	,,
Lillestrøm	0·019	0·0044	,,

The concentration of cæsium-137 per litre precipitation, shown in Fig. 1*C*, also varies in much the same way, but with a somewhat larger difference from site to site. The maximum concentrations in 1959 are found during the periods March–June, and so are the maximum concentrations in 1960. It appears, nevertheless, from Fig. 1*B* and 1*C* that the concentration of cæsium-137 per litre precipitation to a first approximation is proportional to the concentration in ground-level air.

The average cæsium-137 concentration in the total yearly precipitation is:

District	1959	1960		
Bergen	17	3·5	$\mu\mu$c. cæsium-137/l.	precipitation
Røros	13	3·4	,,	,,
Lillestrøm	13	3·3	,,	,,

The rate of deposition of cæsium-137 fall-out, shown in Fig. 1*D*, depends on the amount of precipitation, which is very different from site to site. The maximum fall-out rates in 1959 are found during the periods March to August, and so are the maximum rates in 1960.

The yearly average rate of fall-out is:

District	1959	1960		
Bergen	67	13	$\mu\mu$c. cæsium-137/m.^{2}	per 24 hr.
Røros	10	4·1	,,	,,
Lillestrøm	29	8·9	,,	,,

Fig. 1*E*, showing cumulative cæsium-137 fall-out during January 1959–December 1960, reflects the difference in precipitation from site to site. The total yearly fall-out is:

District	1959	1960	
Bergen	24,300	4,800	$\mu\mu$c. cæsium-137/m.^{2}
Røros	3,800	1,500	,,
Lillestrøm	10,600	3,300	,,

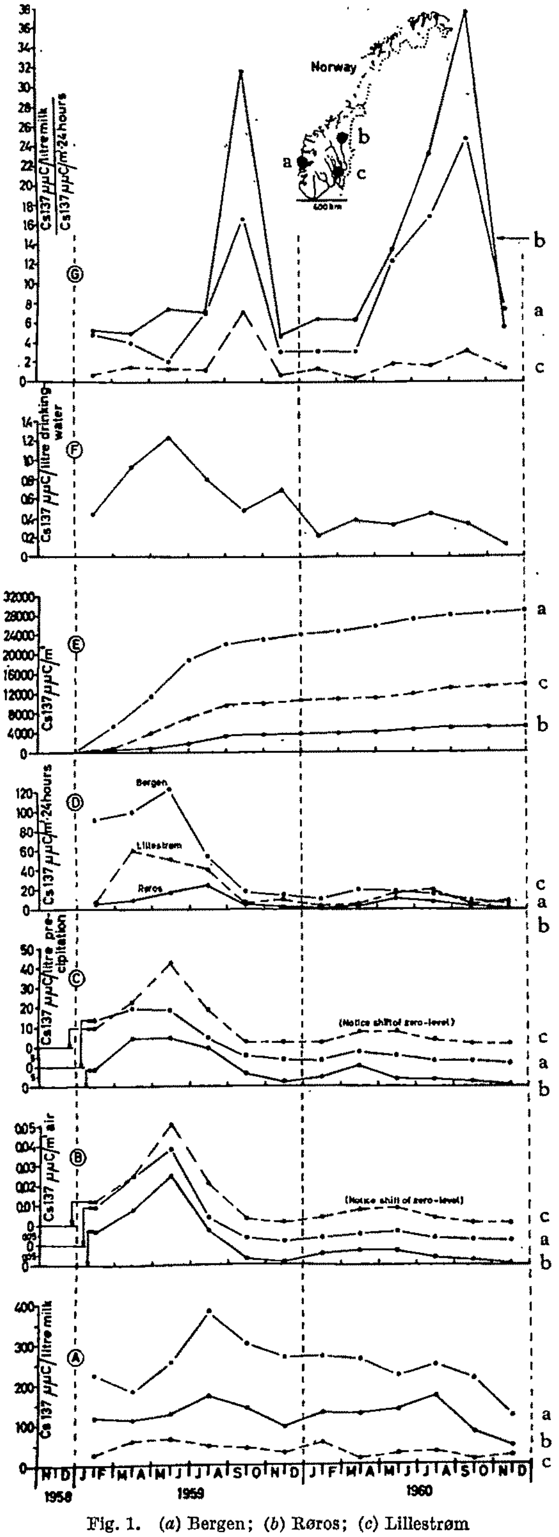

Fig. 1. (*a*) Bergen; (*b*) Røros; (*c*) Lillestrøm

It appears thus that the fall-out at Bergen is about 5 times higher than at Røros and about twice as high as at Lillestrøm.

The average concentration of cæsium-137 in drinking-water samples from 13 places in southern Norway, including Røros, is shown in Fig. 1*F*. The yearly average value is:

1959	1960	
0·8	0·3	μμc. cæsium-137/l. drinking-water

The average cæsium-137 concentration in drinking-water thus is only a few per cent of the average cæsium-137 concentration in precipitation.

The concentration of cæsium-137 in milk, shown in Fig. 1*A*, is also very different from site to site. The yearly average values are:

District	1959	1960	
Bergen	270	230	μμc. cæsium-137/l. milk
Røros	130	120	,, ,,
Lillestrøm	47	29	,, ,,

The concentration of cæsium-137 in milk at Bergen is about twice as high as at Røros and about 7 times higher than at Lillestrøm. The difference thus does not follow the difference in cæsium-137 fall-out.

At all three sites the concentration of cæsium-137 in milk shows a tendency to decrease towards the end of 1960.

The cæsium-137 concentration found in samples of beef during winter and early spring 1960 is:

Bergen	1,760 μμc. cæsium-137/kgm. meat	(average of 2 samples)
Røros	590 ,, ,,	(average of 9 samples)
Lillestrøm	180 ,, ,,	(1 sample)

The variations in cæsium-137 concentrations in meat from district to district appear to follow nearly the same pattern as for milk.

The concentration of cæsium-137 in milk and meat corresponds to an intake by the cow of up to several thousand μμc. cæsium-137 per day. The intake may be through air inhaled, through drinking-water and through fodder. As the air inhaled by a cow is of the order of 200 m.^{3} per day, it is evident that the concentration of less than 0·1 μμc. cæsium/m.^{3} air does not contribute significantly to this intake. The drinking-water intake by a cow is of the order of 50 litres a day. The concentration in drinking-water of less than about 1 μμc. cæsium-137/l. therefore apparently does not represent any important contribution to the daily cæsium-137 intake by the cow. Even during summer time when the cow may be drinking water directly from pools, rivers, lakes, etc., with a somewhat higher concentration than ordinary drinking-water (but still lower than in precipitation), the intake of cæsium-137 by drinking-water does not amount to a large part of the total daily intake by the cow.

Apparently the main contribution to the intake of cæsium-137 by the cow is from cæsium-137 in grass, hay and possibly other fodder. The uptake of cæsium-137 by grass may so far have been mainly direct from rain and air, and less through soil and roots. It might be expected then that the concentration of cæsium-137 in grass and hay and therefore also in milk and meat to a first approximation would be proportional to the rate of cæsium-137 fall-out.

The ratio of cæsium-137/l. milk to cæsium-137/m.^{2} per 24 hr. is shown in Fig. 1*G*. During the winter months November–April, the hay eaten by the cow is from the previous summer. The ratio shown in Fig. 1*G* for the winter months therefore is based on average cæsium-137 fall-out rate during the period May–August of the preceding summer. The average cæsium-137 fall-out rate during these months of 1958 was 47 μμc./m.^{2} per 24 hr. at Bergen and 30 at Lillestrøm. The value at Røros has been calculated to be 23, based on rainfall data from Røros and average concentration per litre precipitation at Bergen and Lillestrøm during May–August 1958. The calculation adds an extra uncertainty to the two first points of the Røros curve in Fig. 1*G*.

It appears from Fig. 1*G* that the ratio of cæsium-137 in milk to cæsium-137 fall-out rate is different from site to site. The yearly average of the 2-monthly values is:

District	1959	1960	
Bergen	6·3	11	$\frac{\mu\mu\text{c. cæsium-137/l. milk}}{\mu\mu\text{c. cæsium-137/m.}^2\text{/24 hr.}}$
Røros	10	15	
Lillestrøm	2·1	1·6	

The difference in ratio may be taken to represent to a first approximation the difference in grazing-field qualities of the three districts, a low ratio corresponding to high grazing-field quality.

For all three districts the ratio-curve shows a maximum during the period September–October, both in 1959 and in 1960. It seems reasonable to relate this increase to the decreasing quality of the grazing fields in the late months of autumn, the slower growing rate of grass giving an increased cumulative effect in the cæsium-137 uptake by the plants.

At Bergen and Røros the ratio is somewhat higher in 1960 than in 1959. As Bergen had an abnormally dry summer in 1960, while Røros had a rather wet and cold summer, this may again be related to lower grazing-field quality during 1960.

On the other hand, the variations in the ratio of cæsium-137 in milk to cæsium-137 fall-out rate may depend on a number of other factors in addition to the grazing-field quality, such as variations in precipitation and fall-out amounts within each district, variations in feeding conditions including amount and type of additional fodder, delay between variation in cæsium-137 intake and resulting variation in cæsium-137 in milk, redistribution of fall-out, and also uncertainties in sampling and measurements.

NUCLEAR MATERIALS AND NUCLEAR CHANGE IN DIFFERENTIATION

By PROF. KENNETH MATHER, C.B.E., F.R.S.
Department of Genetics, University of Birmingham

IN a noteworthy series of experiments, Brink[1,2] has demonstrated that certain alleles at the *R* locus, affecting pigmentation in maize, are capable of showing two different kinds of change. One of these is the familiar phenomenon of mutation. It is sporadic, occurring in this case with frequencies of the order of 1 in 10^5; it is stepwise, in that the products of the mutation do not fall into a graded series; it is undirected; and it results in new alleles which are as stable as that from which they arose. The second type of change differs in all these respects. It is determinate, in that it occurs in 100 per cent of cases under certain conditions; it appears to be capable of giving rise to a graded series of products; it is directed in that a given allele always changes in the same way under the same conditions; and the changed alleles to which it gives rise are metastable, rather than stable, as attenuation of the effect has been observed. Brink terms this second type of change 'paramutation', and shows that the chromosome material on which it depends cannot be the same as that the changes of which appear as normal mutations. In other words, the *R* locus must be dual, containing orthochromatin, which provides the basic gene structure and which by its changes gives rise to true mutations, and parachromatin, which though not of the essence of gene structure nevertheless affects the expression of the gene's action and which by its changes gives rise to paramutations. Paramutation has been established as occurring at one further locus, at least, in maize, and there are indications if not full proof of it in other species[2].

Although at least partial reversion of the *R* paramutants has been observed in maize, the circumstances in which this occurs are not yet clear. In the fly *Sciara coprophila*, however, a similar type of change is to be inferred and the cycle is unambiguous. In the male flies meiosis is replaced by a division which results in one haploid set of chromosomes being eliminated, and this is always the set the male received from his father. The set originating from his mother is handed on to his progeny in which, if they are male, these chromosomes will now be eliminated. The chromosomes have thus changed from 'maternal' to 'paternal' behaviour following passage through the male. Should, however, they be passed by the male to a daughter (from which they are, of course, not eliminated) they will regain 'maternal' behaviour as will be made evident if this daughter in turn passes them on to a son[3].

Further evidence of the complete dependence of change in behaviour of the chromosomes on the sex of the fly through which they passed in the previous generation is supplied by the so-called *X* chromosomes. Each zygote, whatever the sex of the individual destined to develop from it, receives three *X*s, one from the mother and two from the father. The differences between the sexes become apparent at the fifth or sixth cleavage division in the somatic line, for in females one *X* and in males two *X*s are then eliminated from the nucleus. The *X*s to be eliminated are always of paternal origin. The sole remaining *X* of a male is thus maternal, but if it is passed on to a son in the next generation it will show paternal behaviour. One of the remaining *X*s of a female is, of course, maternal but the other is paternal. When passed on by the female to her offspring the two will behave alike as maternals, but if the offspring are male the chromosomes, while continuing to behave alike, will be changed to paternal behaviour as will be exemplified in offspring to which those males give rise in their turn. It has recently been shown that the *X*s owe these curious properties to heterochromatin at the centric end of the chromosome[4].

These changes in the chromosomes of *Sciara* are clearly comparable to paramutation (as indeed Brink points out) in three respects. They are directed; they are determinate, and indeed inevitable according to the sex of the fly which passes the chromosomes to its offspring; and they are metastable, being changed by passage through a fly of the opposite sex. The changes in chromosome behaviour are thus regular consequences of the processes of development and may in fact be described as parts of these processes. We cannot, however, be sure that they in their turn affect subsequent development, for we do not know that the fly would develop differently if a maternal *X* chromosome were to be eliminated instead of a paternal. Indeed, the significance of this differential elimination of paternal chromosomes in *Sciara* is quite obscure.

Various other types of nuclear change are known to occur during development. Some of these, as, for example, the widespread phenomenon of endopolyploidy, are most readily understood not as adaptive changes playing a determinate part in development itself, but simply as the consequences of breakdown in the adjustment of the mechanism of nuclear division in cell-lineages which have come to the end of their history of cell multiplication[5,6]. No question of paramutation arises in this interpretation of endopolyploidy. In other types of change a kind of paramutation may be important. There is cytological evidence, some of it obtained by the use of tritium-labelled thymine[6,7], that the activity of the genes in *Drosophila* changes, and changes differentially, during development. The observations further suggest that these changes must be associated characteristically with the different tissues so that they are determined by the state of the cells in the tissues and indeed are inevitable under the condition of the tissue, just as the chromosome changes of *Sciara* are determined by and inevitable in flies of a given sex. Similar changes in gene action are indicated by King and Briggs's observations[8] on the nuclei of developing frog embryos. I have earlier suggested[9] that these changes are to be interpreted not as changes in the basic content of the genes of the nucleus, but as brought about by the depletion from or accretion to the chromosomes of what I called 'ancillary materials', which, while not of the genes, affect the action of the genes—an interpretation bringing in the same type of change as that which Brink now terms paramutation, with his parachromatin corresponding to my ancillary materials.

In all these cases change is consequent on development, but in none of them is there clear evidence (as opposed to arguable presumption) that the change plays a positive and constructive part in determining the course of future development. The evidence from King and Briggs's frogs is of nuclei which have lost the capacity to sustain the full range of development when put back into the cytoplasm of a fertilized egg. This could indicate (though it does not necessarily do so) no more than a characteristic loss of gene function, just as the cytoplasmic changes associated with certain aspects of differentiation in the fungus *Aspergillus nidulans* are losses of certain capacities rather than constructive gains[6]. There would seem, however, to be no reason in principle why changes of a paramutational type arising during development should not actively and constructively determine the further developmental history of the cells and tissues in which they occur. It is especially tempting to attribute to paramutation the stability which is reached in cells at the end-point of their differentiation. The mechanical control which the chromosome system exercises over nuclear genes gives to these a regularity of behaviour and precision of balance which the cytoplasm could not be expected to emulate, and the evidence from maize and *Sciara* shows the parachromatin or ancillary materials to behave as regularly and be transmitted as precisely as the genes themselves, except, of course, when they are undergoing their determinate changes from one metastable state to another.

Clearly, therefore, paramutational types of change in the chromosomes could play an important part in development. They could not, however, of themselves offer any interpretation of differentiation, for even if we attribute alteration in the behaviour of a cell to such directed and determinate change in its chromosomes, we are still not enabled thereby to see why two sister cells, derived by division of a single mother cell, follow different courses of development. If the parachromatin or ancillary materials share with the other and fully permanent materials of the chromosome the property of equal division in cell reproduction they can no more account of themselves for sister cells following different paths than can those other chromosome materials. So we must still return to the cytoplasm if we are to understand differentiation. The divergences of differentiation must spring basically from differences in the cytoplasmic materials[6,11] even though secondarily it may involve nuclear differences, including paramutational changes, arising as responses to the initial cytoplasmic differences.

We are thus led to inquire whether changes in the cytoplasm can bring about changes in the nucleus, and more particularly paramutational changes. Changes of gross nuclear behaviour during differentiation are, of course, well known and some of them are demonstrably responses to cytoplasmic differences, as, for example, the polymitotic behaviour of nuclei in a mutant strain of maize and the differences in rates of condensation between generative and vegetative nuclei in pollen grains[5,11]. It is known, too, that in bacteria material can exist at times as particles in the cytoplasm and at others as an integral part of the chromosomes, the transition from one state to the other being promoted by specifiable conditions[12]. Furthermore, it is difficult to avoid the conclusion that both Brink's paramutations in maize and the similar changes of chromosomes in *Sciara* involve something outside the chromosomes as an intermediary. In maize, paramutation of the allele on one chromosome is dependent on the presence of an allele not in the same chromosome but in its homologue, so that the paramutagenic action must be exerted extra-chromosomally. In this case the effect may be exerted through the nucleoplasm, as opposed to the extra-nuclear cytoplasm. With the changes of chromosome behaviour in *Sciara* the cytoplasm is more directly implicated since the sex of an individual, and therefore the type of behaviour which its chromosomes will come to assume and express in its offspring, is dependent not on its own but on its mother's genotype and thus on the presence of genes which it itself does not always possess. The cytoplasm would therefore appear to be the intermediary, being conditioned by the genotype of the mother but exerting its effect, of determining the state of the chromosomes, in the offspring. Thus paramutation, like any other nuclear change in development, must be due directly to an action of the cytoplasm (or at least extra-chromosomal plasm) on the nuclear materials and only indirectly on the genes which acted to change and mould that cytoplasm in the first place. The significance of paramutation in development would thus be that it fixed, so to speak, the initially cytoplasmic changes, and gave to them a precision in cell heredity that purely cytoplasmic transmission could not guarantee. In this way paramutational changes, depending on the presence and changes of parachromatin or ancillary materials in the chromosomes, could be of great significance in development. But in differentiation they could have only a derived significance springing from and dependent on the reflexion—one might almost say crystallization—by paramutation of primary changes in the cytoplasm to which indeed differentiation must still ultimately be referred.

It is worth noting, too, that if the normal cytoplasmic progression of differentiation is reflected at least partly in a progression of materials in the chromosomes, these chromosome materials, like the cytoplasm, must either remain unchanged in the cell lineages from which gametes are derived or their progression must come full circle. Otherwise the individuals of the next generation would not start off their development from the same point as did the parents. If developmental change occurs at all in the germ-line, there must be a parachromatinic re-standardization—a clean-up of the ancillary materials in the chromosomes—just as there is of the cytoplasm in the sexual cycle of *Aspergillus glaucus*[10]. This re-standardization is not indeed observed in paramutation at the *R* locus in maize; but here the changes are not characteristic components of development, and indeed if there had been a re-standardization Brink could never have recognized or investigated the phenomena.

Clearly there is need for further studies of paramutation in its relation to the cytoplasm in development and differentiation. This relation may also be of importance in another connexion, for if cytoplasmic change can bring about paramutational alterations of the chromosomes it is possible that external intervention may, through its effects on the cytoplasm, also bring about directed changes of the hereditary materials. The remarkable changes observed by Durrant[13] may be of this kind. He 'conditioned' flax plants by growing them in artificially fertilized soils and found that the plants transmitted the change type not only to the offspring they gave by self-fertilization but also to their crossed progeny, the transmission being equal through pollen and egg. The changes were determinate and specific yet apparently nuclear in transmission: they are capable of obvious interpretation in terms of ancillary materials or paramutation as I have been discussing it. Other alterations of a similar kind can be interpreted in the same way, as may be wider observations of cytoplasmic effects which somehow seem to become attached in transmission to the nucleus (see Roper[14]). In these cases, however, the interpretation is less clear and must remain so until the results of further experiments become available.

THE IONIC CHARACTER OF CHEMICAL BONDS

By E. MOOSER and W. B. PEARSON

Division of Pure Physics, National Research Council, Ottawa, Canada

IN recent years various attempts have been made to determine the effective charges on the atoms of semiconducting compounds from a discussion of the chemical bonding in these materials. While these attempts have not succeeded in reaching their goal, they have led to considerable confusion about the partial ionic character of covalent bonds[1]. In an effort to clear up this confusion we have had many vigorous discussions with our colleagues, and since we believe that the conclusions drawn from these discussions might be of interest to other scientists, we would like to summarize them here.

One of the causes of confusion is the synonymous use of the words 'covalent' and 'homopolar', a mistake which is readily understandable since the simplest examples of covalent bonding—the bonds in the hydrogen molecule and in diamond—are also examples of homopolar bonding, that is, bonding between 'uncharged' atoms. However, the definition of a covalent bond as first given by Langmuir[2] and as adopted by Pauling[3] states that such a bond arises from the 'equal sharing of two electrons' between the two bonded atoms, and thus makes no reference at all to the effective charges on the atoms.

The two distinctly different meanings at present attributed to the term 'ionicity' or 'ionic character of a bond' present a second more serious source of confusion. Lest we contribute further to the confusion we will therefore, in the following, distinguish between an 'effective' and a 'formal' bond ionicity.

Discussing the 'effective' bond ionicity first, we note that an ionic bond results "from the Coulomb attraction of the excess electric charges of oppositely charged ions"[4]. It readily follows from this definition that if two neighbouring atoms (ions) in a molecule or solid carry opposite charges, then the bond between them will have some effective ionic character. Unfortunately, it is difficult to define an unequivocal scale of effective bond ionicity, because whereas zero ionic character obviously corresponds to zero charges on the ligands, it is sometimes not immediately clear to which degree of ionization of the ligands 100 per cent effective bond ionicity has to be ascribed. However, by convention a bond between two atoms is normally called 100 per cent ionic if the atoms are ionized to the extent that at least one of them acquires a noble gas shell. This convention allows us to call a compound purely ionic if all its bonds have 100 per cent effective ionic character. Moreover, because an ion with a noble gas shell cannot form any covalent bonds, the convention assures that a bond with 100 per cent ionic character cannot have a covalent component.

It follows from the above discussion that the percentage i_e of effective ionic character of the bond between two atoms A and B is closely related to the 'effective charges' q_A and q_B on these atoms. Indeed, if q_{0A} and q_{0B} are the charges which the two atoms would carry if the bond between them were completely ionic, then:

$$i_e = \frac{q_A}{q_{0A}} \times 100 = \frac{q_B}{q_{0B}} \times 100 \qquad (1)$$

We note that the definition of the effective ionic character of a bond as given by (1) is identical with that used by Pauling[5] in discussing the relationship between bond ionicity and dipole moment μ of the hydrogen halogenide molecules (see also Hannay and Smyth[6]). Indeed, if r_0 is the equilibrium distance between the two atoms of such a molecule, we find for the effective charges $q_A = -q_B = q$ on the atoms:

$$q = \mu / r_0 \qquad (2)$$

and hence for the effective bond ionicity:

$$i_e = \frac{\mu}{r_0 q_{0A}} \times 100 = -\frac{\mu}{r_0 q_{0B}} \times 100 = \frac{\mu}{r_0 e} \times 100 \qquad (3)$$

where e is the electronic charge.

Contrary to the effective bond ionicity, the 'formal bond ionicity' is not related to any quantity such as the effective charge, which is at least in principle measurable. (For diatomic molecules the effective charge is defined by (2) and hence can readily be determined experimentally. Unfortunately, this definition cannot be extended to include complex molecules and solids. Nevertheless, any discussion of effective bond ionicities implies that effective charges can, at least in principle, be measured, because the ionic bond itself is, after all, defined in terms of such charges.)

The formal bond ionicity is a purely theoretical concept, and its numerical value depends on the approximation used in describing a bond and not on the actual properties of this bond.

Because no method is available for solving many-electron problems accurately, it is often assumed[3,7] that the bonds in molecules or solids can, with sufficient accuracy, be described as resulting from the resonance of these molecules or solids among different valence structures. Let us discuss briefly a diatomic molecule AB the components of which have one valence electron each (monovalent atoms). Chemical and physical intuition tells us that it is reasonable in this case to consider the following valence structures:

$$A:B \qquad A^+B^- \qquad A^-B^+$$

Corresponding to equal sharing of the valence electrons by the two partners, the first structure is called 'covalent'. For obvious reasons, the other two structures are both called ionic.

Let $\Psi_{A:B}$, $\Psi_{A^+B^-}$ and $\Psi_{A^-B^+}$ be three properly chosen two-electron wave-functions corresponding to the three valence structures. With these functions we form the linear combination:

$$\Psi = a\Psi_{A:B} + b\Psi_{A^+B^-} + c\Psi_{A^-B^+} \qquad (4)$$

and determine the coefficients b/a and c/a such as to minimize the integral:

$$E = \frac{\int \Psi^* H \Psi d\tau}{\int \Psi^* \Psi d\tau} \qquad (5)$$

Substituting these coefficients in (4), we obtain the best wave-function which can be constructed by combining linearly $\Psi_{A:B}$, $\Psi_{A^+B^-}$ and $\Psi_{A^-B^+}$. The formal ionic character of the bond $A - B$ is then determined by the extent (measured by the coefficients b/a and c/a) to which the structures A^+B^- and A^-B^+ contribute to Ψ.

It is obvious from this discussion that the formal ionic character of a bond is defined only with respect to the particular approximation used in describing the bond. Thus if, for example, the electronegativity of atom B is much larger than that of atom A, it is sufficient to consider only the first two of the above valence structures, and (4) takes the form:

$$\Psi = a\Psi_{A:B} + b\Psi_{A^+B^-} \qquad (6)$$

The corresponding percentage i_f of formal ionic character of the bond then is given by:

$$i_f = \frac{(b/a)^2}{1 + (b/a)^2} \times 100 \qquad (7)$$

The two valence structures considered here in describing the bond in a molecule of monovalent atoms are obviously the same as those defining the scale of effective bond ionicity in such a molecule. It is permissible therefore to put:

$$i_f = i_e \qquad (8)$$

and one can in this case determine the only free parameter in (6), namely b/a, from the experimental value of i_e, thereby avoiding the cumbersome process of minimizing (5).

Equation (8) is perhaps the cause of all the confusion about bond ionicities. We would like to emphasize, therefore, that in spite of the conditional validity of (8), formal and effective bond ionicities are not identical, and one does well to distinguish carefully between them, particularly when discussing solids. Moreover, (8) should never be interpreted as implying that the effective ionic character of a bond can be derived from a formal bond ionicity. Indeed, if the effective ionicity of a bond is not known, the value of any formal ionicity attributed to this bond is always arbitrary, because it is necessarily based on arbitrary mixing of arbitrary, if plausible, valence structures.

To demonstrate the confusion which can arise from the indiscriminate use of the term 'bond ionicity', let us briefly dwell on a fallacious but often repeated discussion of the bonding in semiconductors of the zincblende type. This discussion, which has perhaps been instigated by Pauling's somewhat misleading account of the bonding in AlP (ref. 8), will here be given for zinc blende itself. The tetrahedral bonds in this compound are said to arise from resonance among the following two valence structures:

$$Zn^{2-}S^{2+} \qquad Zn^{2+}S^{2-}$$

The first of these is referred to as the 'extreme covalent' structure, because it leaves each of the components with four valence electrons which can be shared in the formation of the maximum number of four tetrahedral bonds. The second structure is called 100 per cent ionic since it corresponds to a noble-gas configuration on both the zinc and the sulphur ions. These valence structures are taken to define the scale of bond ionicity (one is left guessing whether it is formal or effective ionicity), so that the bonds in the hypothetical 'neutral-bonded' Zn^0S^0 obtain 50 per cent ionic character[1]. Since sulphur is more electronegative than zinc, it is then concluded that in the crystal each sulphur carries some negative and each zinc the same amount of positive charge. Hence, the argument goes on, the bonds in ZnS are more than 50 per cent ionic. Such a statement is very misleading indeed, and matters are only made worse if, as has been done, one goes a step further and calls ZnS a compound with more than 50 per cent ionic character.

We should, perhaps, recall here that the generally accepted definition of the covalent bond as given earlier leaves the effective charges on the ligands unspecified. To define the zero of effective bond ionicity by an arbitrary valence structure such as $Zn^{2-}S^{2+}$ is therefore meaningless, even though one might choose to call the structure 'extreme covalent'. Finally, we should like to repeat that out of any discussion of formal bond ionicities one can never obtain more information than was originally put in. In particular, any attempts such as have been made to determine effective charges from formal bond ionicities are bound to fail.

EFFECT OF TEMPERATURE ON ADHESION TO GLASS AND HISTOGENETIC COHESION OF DISSOCIATED CELLS

By PROF. A. MOSCONA

Department of Zoology, University of Chicago

ONE of the chief attributes of metazoan cells is their ability to cohere and interact mutually into integrated, multicellular systems. Though the mechanisms of cell cohesion and the role of cell contact in development and in tissue function have had a long history of interest and speculation, recent reviews of these problems[1] clearly underscore the paucity of basic information on various important aspects. Among the theoretically and practically more obvious and pressing questions is that of the effects of temperature on the capacity of cells to adhere to various substrates and to each other. Though such information would seem prerequisite for a systematic inquiry into the mechanisms of adhesion and interaction of cells, the point has been surprisingly little studied. The methodology of dissociation and aggregation of embryonic cells[2] affords a direct approach to these problems; in connexion with present work on tissue-synthesis *in vitro* from dissociated cells[3,4], the question of temperature and cell adhesion was examined and some of the findings are reported here briefly.

Chemically dissociated cells[2,4] from neural-retina, liver and kidney (mesonephros) of 7-day chick embryos were used throughout this work. The cells were suspended in a standard culture medium (Eagle's basal medium with 1 per cent glutamine, plus 10 per cent horse serum, 2 per cent fresh embryo extract in Tyrode's solution, and 50 μ/c.c. penicillin-streptomycin).

Adhesion to glass. 2 c.c. aliquots of cell suspension (10^4 cells/ml.) were distributed into flat, 15-ml. T-flasks, filled with 5 per cent air containing carbon dioxide and sealed. Groups of flasks were kept at 38°, 30°, 25° and 15° C. The cells settled rapidly on the floor of the flasks and were not disturbed for 24 hr. They were then examined and the number of attached and unattached cells determined.

The three kinds of cell populations tested gave essentially similar results. At 38° C., 85–90 per cent of cells adhered firmly to the glass and were not dislodged by gentle flushing. The individual attached cells were flattened or rounded; others were in small spheroid clusters also stably attached to the glass. At 30°, about 60 per cent of the cells were firmly attached; at 25°, less than 40 per cent adhered stably. At 15°, cells did not adhere; even when left for 72 hr. in continuous contact with the floor of the flasks there was no attachment. When cultures from sub-optimal temperatures were transferred to 38°, there was rapid and abundant attachment of cells to the flask. It appears, therefore, that in the present case adhesion of cells to glass depended on temperature-sensitive processes which were completely, but reversibly, inhibited at 15° C. Interpretations of the mechanism of cell adhesion in such and similar systems must, therefore, account for the temperature-dependence of this cellular activity.

Histogenetic cohesion. To find out whether cohesion and histogenetic bonding of dissociated cells also were dependent on temperature, a procedure was sought which would: (1) render it possible to bring discrete cells rapidly into contact, independently of their capacity for locomotion, and without forceful packing (as by centrifugation); (2) reveal differences in stability and effectiveness of intercellular contacts under diverse testing conditions; (3) yield consistent results in a form amenable to quantitation. These requirements are adequately met by the 'rotation-mediated cell aggregation' procedure, described in detail elsewhere[4]. Erlenmeyer flasks with cell suspension are rotated on a gyratory shaker with a ¾-in. diameter motion. Due to the spinning flow of the liquid, all the cells are rapidly concentrated in the middle of the vortex and, if capable of cohesion, become soon bound into compact aggregates in which they construct tissue. The size distribution of aggregates thus formed reflects an equilibrium between cell cohesiveness under the given conditions, and the shearing forces of the system: the lesser the capacity of cells to cohere (or the fewer the number of cohesive cells, or the stronger the shearing forces), the smaller the resulting aggregates. All experimental parameters in this system are rigorously controllable, and under standard conditions diagnostically consistent 'aggregation patterns' are obtained, characteristic for diverse cellular and environmental situations.

In the present case, aggregation patterns produced at 38° C. by suspensions of 7-day embryonic chick cells (as above) served as a basis for testing the effects of lower temperatures on cell cohesion.

3-ml. aliquots of cell suspension (3×10^5 cells/ml.) were dispensed into 25-ml. Erlenmeyer flasks and rotated at 70 r.p.m. at 38°, 30°, 25° and 15° C. After 24 hr., size distribution of aggregates and number of free cells in each culture were determined. At 30° and 25° there was a significant and consistent decrease in size of aggregates of all cell types tested, illustrated for neural-retina cells in Figs. 1 and 2. This was accompanied by an increase in number of free cells. At 15° the cells did not cohere at all, and aggregates were not formed; even when maintained in continuous contact for 72 hr. at this temperature, the cells remained entirely discrete. Transferred to 38° C. such cells cohered into histogenetically effective aggregates. It should be pointed out that 15° C. is not the starting temperature for complete inhibition of cell cohesion; more recent results indicate that neural-retina cells may not cohere at about 18° C. and that sensitivity in this respect varies with cell type, state and culture medium.

The foregoing results reveal a clear correlation between temperature and ability of freshly dissociated avian embryonic cells to adhere to glass or to cohere mutually. The finding that at 15° C. cells are completely unable to become attached, though in prolonged and continuous contact, appears particularly useful towards further study of the mechanism of cell adhesion. It indicates that simple reactions between divalent cations (calcium, magnesium), or other first-order physico-chemical effects cannot be exclusively responsible for cell adhesion, as such reactions are unlikely to be persistently inhibited at 15° C. It also suggests that the exogenous molecules prerequisite for normal adhesion of cells (divalent cations, serum proteins[3,5]) provide only parts of the actual mechanism or contribute otherwise partially to its effective function, and that endogenous thermo-sensitive processes may have a highly important, perhaps primary, role in this cellular activity[6]. It is therefore proposed that cell adhesion may depend on metabolic sequences and closely reflect the metabolic economy of the cells ; therefore, that it is not merely a result of coupling between stable surfaces, but also a function of the synthetic activities of cells. Assuming this, cell adhesiveness would be expected to vary with different functional states of cells ; evidence to this effect is forthcoming, and can also be inferred from various, indirectly related, data in the literature.

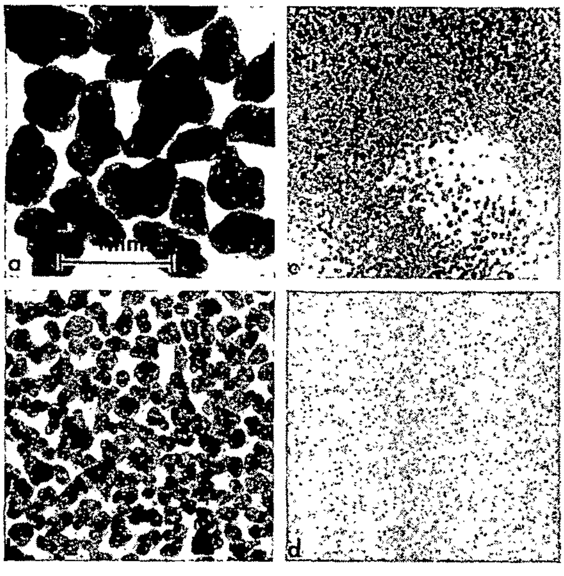

Fig. 1. 24-hr. aggregates of dissociated neural-retina cells (7-day chick embryo) formed in rotating cultures (70 r.p.m.) at 38° (*a*); 30° (*b*) ; 25° (*c*) and 15° C. (*d*); the cells remained separate

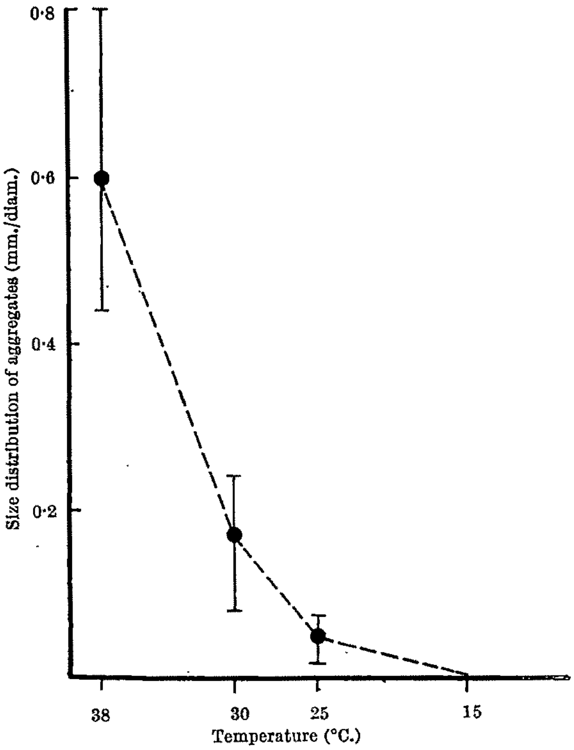

Fig. 2. Effect of temperature on size distribution of aggregates of dissociated neural-retina cells

The present findings appear to fit in with the working assumption[3] that (1) adhesion and histogenetic bonding of cells involve the production and organization between cells of mucoprotein-containing extracellular materials, the formation or effective function of which requires divalent cations and certain large molecules in the cellular environment ; (2) rate of formation and properties of extracellular materials vary with type, age, metabolic pattern and treatment of cells; at low temperatures synthesis of extracellular materials is impaired resulting in failure of dissociated cells to become effectively attached.

This work was supported by grants from the National Cancer Institute, U.S. Public Health Service (*C*–4274), and from the Dr. Wallace C. and Clara A. Abbott Fund of the University of Chicago.

MAGNETIC SUSCEPTIBILITY OF NORMAL LIVER AND TRANSPLANTABLE HEPATOMA TISSUE

By FRANK E. SENFTLE
United States Geological Survey, Washington, D.C.

AND

ARTHUR THORPE
Howard University, Washington, D.C.

IN 1948, Barnothy[1] found that young female mice, when placed in a (3–6) × 10^3 oersteds magnetic field, underwent a temporary retardation of growth. The magnetic field apparently hindered mitosis. Barnothy *et al.*[2] reported a significant drop in the segmented leukocyte count in mice while confined in a magnetic field, whereas when they were removed from the field the count increased to peak values more than 100 per cent higher than the normal value. From these and other related experiments[2–5] with biological materials in magnetic fields, it can be inferred that a magnetic field may have a significant effect on growth of cancer cells. In support of this thesis, Barnothy reports[6] that at the University of Budapest he obtained good recovery results on albino mice inoculated with *T* 2146 adenocarcinoma. Of the animals placed in an inhomogeneous magnetic field of 3,000–3,500 oersteds, there was loss of tumour in 5 and complete recovery in 4 cases out of 6, whereas there was 100 per cent mortality in the control animals. It has thus become increasingly clear that as a next step a more fundamental study of the magnetic properties of cancer and normal cells should be made. A comparative study was therefore undertaken of the magnetic susceptibilities of both types of cells. The results in this article indicate that the magnetic properties of transplanted hepatoma and normal liver tissue are different, and that the difference is probably associated with the way in which the water is held by the respective cells.

As an exploratory experiment, measurements were made on the normal and host tissue from the same organ (human larynx) which had been preserved in formaldehyde. The specimens were thoroughly dried, and several milligrams of tissue were removed with a glass knife for each measurement. No steel instruments were used in order to avoid unnecessary ferromagnetic contamination. The average magnetic susceptibility at room temperature of the tumour and normal tissue from this organ was $(-0{\cdot}61 \pm 0{\cdot}008) \times 10^{-6}$ e.m.u./gm. and $(-0{\cdot}57 \pm 0{\cdot}007) \times 10^{-6}$ e.m.u./gm. respectively. The difference is considered significant as it is several times the experimental error.

In view of these results, two series of controlled experiments were performed with rats. By means of trocar inoculation, a transplantable hepatoma was allowed to develop in some of the rats for 4–8 weeks. The tumour-bearing and control animals were then killed and the liver and transplanted tumour tissue removed. As soon as the tissue was removed from an animal, it was quick-frozen in liquid nitrogen to prevent any serious deterioration of the cells and remained there until the measurements could be made. The specimens were then removed from the liquid nitrogen and a small sample ($\approx$10 mgm.) was removed by cracking the frozen organ in a porcelain mortar. The entire sample preparation was performed in a refrigerated room held to within a few degrees of 263° K. so as to preclude any thawing of the specimen.

Although a steel scalpel was used to remove the tissue from the animal, non-ferromagnetic instruments were used thereafter in handling the samples to prevent contamination. By selecting a sample of frozen tissue from below the surface of the specimen ferromagnetic contamination could be minimized. However, to ensure further against this effect, each sample was measured at several magnetic field strengths. The apparent magnetic susceptibilities were then plotted against the reciprocal field (see Fig. 1) at each field strength after the manner of Owen[7] and Honda[8]. As ferromagnetism is dependent on field, the ordinal intercept is thus the susceptibility corrected for ferromagnetic impurity.

The magnetic susceptibility measurements were made by a modified Faraday method using a sensitive quartz helical spring balance described elsewhere[9]. The balance was placed in the same refrigerated room described above. Considerable difficulty was encountered in making the measurements due to the change in mass caused by evaporation of moisture at certain temperatures. Because the moisture content of the cold room was reasonably constant, little difficulty was experienced in making the measurements at 263° K. in air. At lower temperatures, however, carbon dioxide and some of the rare gases will condense out of the air, and hence helium had to be used as a heat transfer gas. As the helium was very dry, the sample tended to lose water. For each of the measurements in helium at temperatures between 170° K. and 263° K., the mass of the sample was remeasured using the quartz helix without a magnetic field, that is, as an analytical balance. In this way, a correction for loss of moisture could easily be made. At temperatures below 170° K., the vapour pressure of ice is so low that the change in mass due to loss of moisture is negligible.

In the first experimental series, two rats of the $A \times C$ strain were used for the tests. The tumour was allowed to grow for four weeks after inoculation in one rat, the other was used as a control. At the end of this period, the animals were lightly anæsthetized, and the liver and tumour tissue removed and

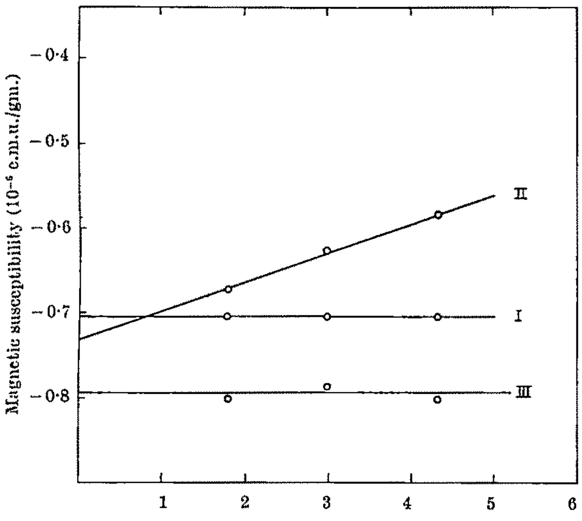

Fig. 1. Magnetic susceptibility of normal liver tissue from control animal (I) and liver (II) and transplanted hepatoma tissue (III) from tumour-bearing rat as a function of the reciprocal magnetic field

frozen. After loading a small sample on the balance, helium was admitted to the system and the temperature immediately dropped to liquid nitrogen temperature. By using this technique on each specimen of this series, a minimum amount of water was lost by evaporation. Re-measurement at room temperature in moist air allowed a correction to be made for this small loss.

All the measurements of this series were made at liquid-nitrogen temperature for another reason. If the cancer cells contained an abnormal amount of some paramagnetic impurity as, for example, some free radical, one would expect a paramagnetic component in addition to the basic diamagnetism of the cells. As the positive magnetic susceptibility of many paramagnetic substances increases as the temperature is lowered, it was thought worth while to take advantage of this enhancement if it existed in these specimens.

The susceptibilities plotted against the reciprocal field are shown in Fig. 1. The susceptibilities corrected for ferromagnetism (ordinal intercept values) of all the specimens are diamagnetic, the tumour tissue being more diamagnetic than the normal tissue as it was in the previous measurements. Although the results of the previous experiment on larynx tissue should not be compared too closely with these because of the differences in kinds of tissue, the pattern of the results is similar. The fact that the susceptibilities at the lower temperature are more diamagnetic would seem to suggest that the major differences between the normal and tumour tissue are not due to the presence of a paramagnetic substance.

The dependence on field shown in Fig. 1 for the liver from the tumour-bearing host rat indicates ferromagnetic impurity. At first this was thought to be a significant property of the tissue, but subsequent repeated measurements on samples of liver from other tumour-bearing host rats lead us to believe that this impurity was probably contamination.

To substantiate the results of this experiment, tissue from three more rats with transplanted hepatoma No. 3683 and three normal control animals was measured. To obtain a better temperature comparison with the first series, the measurements in this second series were first made at 263° K. in air. The results shown in Table 1 again show the same pattern, but in this instance are comparable with those in Fig. 1. The diamagnetic susceptibilities are lower, and the differences between the susceptibilities of the two kinds of tissue are smaller.

Table 1. MAGNETIC SUSCEPTIBILITY OF TUMOUR AND NORMAL TISSUE OF RATS*

Sample No.	Magnetic susceptibility (in 10^{-6} e.m.u./gm.)

II-5	− 0·649	
II-6	− 0·634	

* All the results have been corrected for ferromagnetic impurity, and have been taken at 263° K.

To explain these results better, the susceptibilities of duplicate samples of the same specimens listed in Table 1 were determined as a function of temperature from 77° K. to 263° K. No change was observed in the force on the sample as the temperature of the system was dropped from 263° K. to about 160° K. Therefore, independence of temperature was assumed in this region. Below 160° K., the force on the sample began to change and more measurements were made down to 77° K.

The results shown in Fig. 2 throw considerable light on the problem. The results for the tissue from the tumorous animals resemble a change-of-state curve exhibited by many substances[10]. As the change in the susceptibility at about 130–140° K. is so pronounced, it is not likely that it could be caused by a substance present in trace amounts. Due to high concentration in cell tissue, water or ice must be suspected. The magnetic susceptibility of ice is not well known in this temperature-range, so a series of measurements on ice was made following the same general procedure as outlined here. The

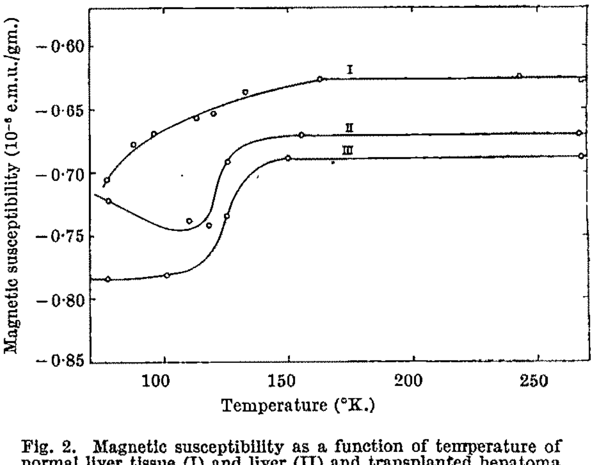

Fig. 2. Magnetic susceptibility as a function of temperature of normal liver tissue (I) and liver (II) and transplanted hepatoma No. 3683 tissue (III) from tumour-bearing rat

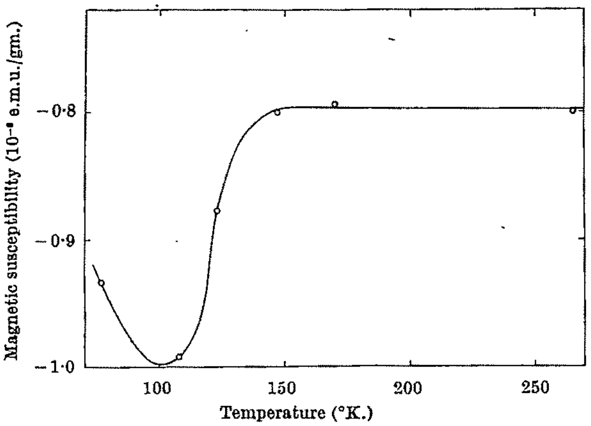

Fig. 3. Magnetic susceptibility of ice from distilled water as a function of temperature

results are shown in Fig. 3. The shape of the curve is so similar to those of the hepatoma and liver of the tumour-bearing host that one is led to conclude that the general feature of these curves is primarily due to the magnetic properties of ice rather than of the tissue itself. The break in the curve at about 130–140° K. is undoubtedly due to the change in state. Ice changes from hexagonal to the low-temperature cubic form at some temperature near 173° K. [11]. However, below 133° K., Lisgarten and Blackman[12] have shown that the X-ray diffraction pattern becomes diffuse. It is probably a change in crystal size or strain which accounts for the diffuse X-ray pattern and also the increase in diamagnetism of ice at about the same temperature.

To substantiate further the fact that changes in the magnetic properties of water are the chief reason for the characteristic form of the magnetic susceptibility curve of tumour tissue, an attempt was made to remove the water in the tumour cells by evacuation at 263° K. The residual tissue, however, was so spongy that it was extremely difficult to get enough material for the measurement in the homogeneous part of the magnetic field of the magnets. As an alternative, the effects of water in egg whites was measured for comparison. Curve I of Fig. 4 shows the change in the magnetic susceptibility of fresh egg white as a function of temperature. The results are similar to that of pure water and also the tumour tissue. The egg white was then slowly evacuated for 48 hr. at room temperature, and a 14·7-mgm. sample was loaded on the magnetic balance. The balance chamber was then further evacuated for an additional 18 hr. until constant weight was achieved. The subsequent susceptibility measurements (curve II, Fig. 4) show the absence of the magnetic properties of water. From these experiments it is reasonable to assume that the general features of the susceptibility curves of the tumour tissue are essentially due to the effects of water.

As water is diamagnetic ($-0{\cdot}7^{+} \times 10^{-6}$ e.m.u./gm. at 273° K.) and as livers of tumour-bearing animals are known to contain more water than normal liver tissue[13–15], the more diamagnetic character of the liver tissue from the tumour-bearing host compared with normal tissue is reasonable. Apparently, the same is true of hepatoma, although some tumours are known to contain less water[15]. From the magnetic susceptibility of water at 263° K. (Fig. 3) and of normal and tumour tissue (Fig. 2), an increase in the water content of the host tissue over the normal tissue of 5·8 and 8·5 per cent can be calculated for the liver and hepatoma respectively. This agrees with the fact that hepatomas generally have a higher content of water than normal liver[15,16]. It is therefore very probable that the increased diamagnetism of the liver and tumour tissue in the host is due to an increase in water content compared with the normal tissue.

An interesting feature of the results in Fig. 2 is the shape of the susceptibility curves for the tissue from the control and host animals. The change in state pattern of water does not appear in the normal tissue, and yet it is known that normal liver tissue contains about 70 per cent water. At least part of the water in the normal and tumour tissue does not go through the normal phase changes, that is, the molecules do not appear to be free to associate in the usual manner. As discussed by Gortner[17], many experiments have been performed which show that forces at the surface of lyophilic colloids tend to bind water with greater force than the usual forces of association which ultimately arrange water molecules in an ice crystal lattice. Bound water in gelatin has been shown to remain unfrozen down to temperatures as low as 170° K. (ref. 18), and probably will remain unfrozen to much lower temperatures. The perplexing problem in trying to explain the magnetic susceptibility of normal tissue by bound water is the amount present. It is difficult to see why essentially all the normal tissue water is bound, as would have to be the case to explain the results in Fig. 2. Most investigators have reported bound-water values of 25–30 per cent or less for colloidal materials[17], which are considerably

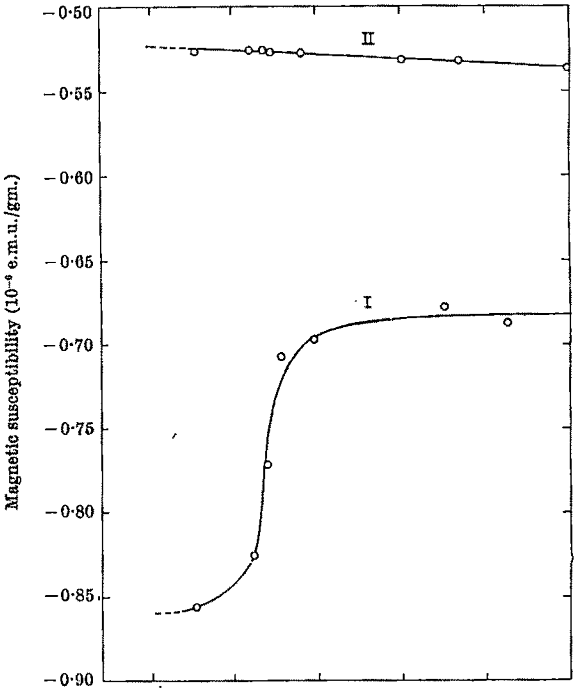

Fig. 4. Magnetic susceptibility of fresh egg white (I) and vacuum dehydrated egg white (II) as a function of temperature

less than is indicated by these measurements. Further work will have to be done to confirm the amount of bound water in normal tissue.

The decrease in the diamagnetism below 110° K. in the liver tissue and not in the tumour of the tumour-bearing host is not surprising. A small amount of paramagnetic or ferromagnetic impurity could easily account for the rise in the curve at the lower temperatures. It is known, for example, that both iron and cobalt are present in increased concentrations in the liver of tumour-bearing hosts.

In summary, it has been shown that the magnetic properties of transplanted hepatoma and normal liver tissue are different, and that the difference is probably due in a large part to the amount and form of the water held by the cells in the two types of tissue. The water in the normal cells appears to be bound, whereas that in the tumour tissue appears to be partially free water; however, this hypothesis will have to be confirmed by further experiment. If the pattern of magnetic susceptibility is found to be generally true for various kinds of tumour tissue, the measurement of magnetic susceptibility may be used as a diagnostic tool. With some refinements the method could be used on specimens as small as 1–2 mgm.

We wish to acknowledge the interest and help of various members of the National Cancer Institute. In particular, we wish to thank Drs. R. Kaiser, S. Inghram, A. Hilberg and Mr. P. Lawrence for their stimulating discussions, Dr. H. P. Morris for supplying the test animals and transplanted hepatomas, and Mr. D. Trainor who helped to prepare the specimens. We are also grateful to Dr. H. Branson, of Harvard University, for his continued interest in this work.

ACTIVATION OF FERRITIN SYNTHESIS AND INDUCTION OF CHANGES IN FINE STRUCTURE IN HELA CELLS *IN VITRO*: IMPLICATIONS FOR PROTEIN SYNTHESIS

By Prof. G. W. RICHTER

Department of Pathology, Cornell University Medical College,
New York 21

WORK in my laboratory has provided evidence that the synthesis of the iron-containing protein, ferritin, can be activated in cells grown *in vitro* in tissue cultures. HeLa cells growing in a semi-synthetic medium produced ferritin within 4 hr. following addition of small quantities of ferrous sulphate to the medium. 5γ of iron per ml. of medium sufficed to bring about this result.

A strain of HeLa cells was obtained from Microbiological Associates, Inc., Bethesda, Maryland, and the cells were grown in an Earle–Eagle medium containing amino-acids, vitamins, minerals (excluding iron), streptomycin, penicillin, and horse serum (10 per cent by vol.). No iron was demonstrable in this medium by standard analytical tests sensitive to concentrations as low as 0·03 γ/ml.[1]. Control tests for iron, performed on acid digests of packed HeLa cells, grown during 2 weeks in 5 ml. of this medium, revealed minute amounts of iron, consistent with the presence of iron-containing enzymes.

Ferritin was demonstrated by means of electron microscopy on sectioned cells[2,3], and by chemical isolation using cadmium sulphate[4]. Furthermore, using established procedures[5,6], both ferritin and apoferritin were isolated from cell homogenates with an ultracentrifuge, and were later identified in the electron microscope[7] and by means of precipitin tests with specific antisera, obtained from rabbits after immunization with solutions of crystalline human ferritin. Trivalent iron in the cytoplasm—and occasionally in the nuclei—of cells treated with ferrous sulphate was shown to be present by means of the Prussian blue test.

Sub-cultures carried in individual flasks or bottles for approximately one week were used. Measured quantities of freshly prepared sterile solutions of ferrous sulphate were added to yield final concentrations of iron ranging from 2 to 15 γ/ml. Afterwards, cells were taken for examination after 2, 4, 24 hr., and at intervals up to 2 weeks. In cultures kept longer than 3 days the medium was changed periodically, and to some of these ferrous sulphate was added a second time. Cells from control cultures, to which no iron had been added, were examined concurrently.

Representative results obtained with HeLa cells are shown in Table 1. The findings indicate clearly that ferritin synthesis occurred within 4 hr. after addition of ferrous sulphate. As judged from electron micrographs and from yields of chemical

Table 1. Production of Ferritin (Apoferritin) by HeLa Cells

Ferrous sulphate γ/ml. medium	Interval	Tests for ferritin (apoferritin)			
		Cell extracts		Crystallization (cadmium sulphate)	Electron microscopy of cells (*e*)
		Precipitin tests	Electron microscopy (*d*)		
0	0 (*a*)	–	–	–	–
5	2 hr.	–	*A*	not done	–
5	4 hr.	±	*F* and *A*	,, ,,	+
5	24 hr.	+	*F* and *A*	,, ,,	+ +
5	48 hr.	+	*F* and *A*	,, ,,	+ + +
5 (*b*)	5 days	+	*F* and *A*	+	+ + + +
5 (*c*)	14 days	+	*F* and *A*	+	+ + + +

Notes: (*a*) Control cultures, same age as others. No iron added. (*b*) Medium changed after 3 days without addition of iron. (*c*) Medium changed twice. Ferrous sulphate added each time. (*d*) *F*, ferritin present; *A*, apoferritin present. Apoferritin identified by means of negative staining (ref. 7). (*e*) Only ferritin can be identified with certainty by this method.

extractions, the quantities of ferritin accumulating in HeLa cells increased as time went on. But it was also found that some HeLa cells from cultures grown in the presence of ferrous sulphate contained little or no ferritin. It is not clear at present whether these were cells that had synthesized little or no ferritin; whether they had synthesized it and disgorged it; or whether only apoferritin—not clearly visible in electron micrographs of sectioned cells—was present.

The earliest accumulations of ferritin were located within discrete cytoplasmic bodies, up to 1μ in cross-section, and similar in appearance to the 'siderosomes' described previously by me[2]. However, these bodies varied considerably. Some resembled 'myelin figures', others had a complex system of tubules, and still others also contained a relatively homogeneous material of low density to electrons (apoferritin ?). Frequently, they were situated in a cell segment close to an indenture in the nucleus. Cytoplasmic bodies of a novel kind were noted in HeLa cells taken three or more days after addition of iron (Fig. 1). Characteristically, those bodies were delimited by membranes and contained material of high density to electrons. In profile this material appeared in the form of circinate structures, with hollow centres and with walls measuring up to 200 Å. in cross-section. Arrays of ferritin molecules often adjoined the dense walls. Cytoplasmic deposits of partly hydrated ferric oxide[8] were also noted. In samples taken from cultures 24 hr. after addition of ferrous sulphate a small proportion of cells contained intranuclear collections of ferritin molecules.

No ferritin or apoferritin was found in cells from control cultures to which no iron had been added.

Thus, the addition of ferrous sulphate to the HeLa cell cultures had two consequences: apoferritin synthesis, and the reaction of the apoferritin with iron, yielding ferritin.

Further results have indicated that apoferritin synthesis can be initiated in HeLa cells by very small concentrations of iron (< 1 γ/ml.), and that apoferritin is synthesized within 2 hr. after addition of iron—before ferritin iron micelles are detected in cells with the electron microscope. This is in agreement with evidence showing that in the liver apoferritin is synthesized first, and iron incorporated later into apoferritin[9].

It is not clear yet whether any of the aforementioned cytoplasmic organelles are sites of apoferritin synthesis, whether they are involved in the incorporation of iron into apoferritin, or whether they are concerned with the disposition of ferritin or apoferritin following synthesis elsewhere in the cell. Judging from present hypotheses on the mechanism of protein synthesis, the production of apoferritin might be initiated by intranuclear synthesis of specific RNA. The latter may then be moved into the cytoplasm[10].

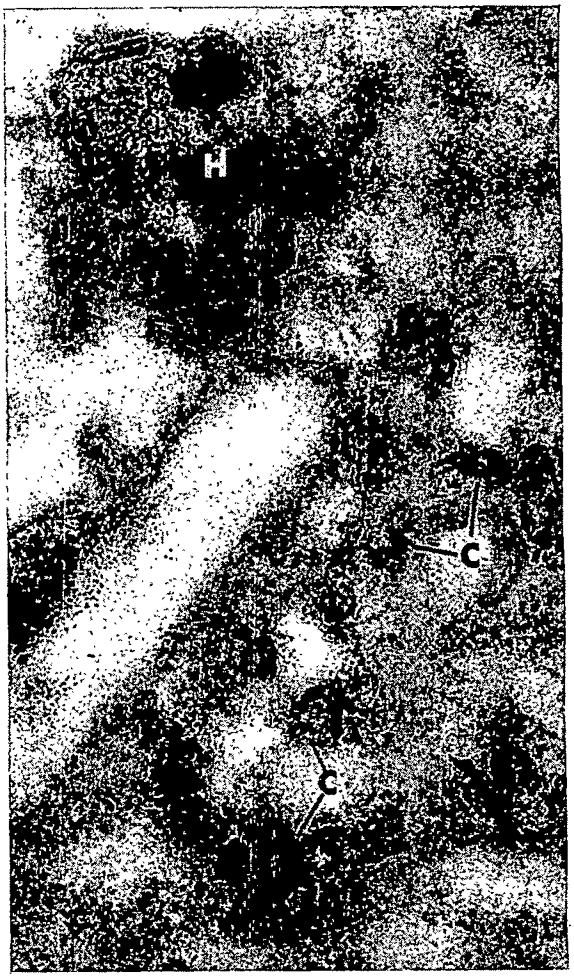

Fig. 1. Part of cytoplasm of HeLa cell from culture kept 3 days in medium containing 5γ of iron per ml. Note organelle (*H*) at upper left, delimited by membrane and containing: (1) ferritin molecules represented by small particles, ~ 60 Å diam. (FeOOH micelles); (2) larger opaque bodies. A larger organelle (lower right) contains bodies (*C*) with opaque walls (~ 200 Å.), and non-opaque centres. Ferritin molecules are situated close to these bodies and within them. (× 100,000)

One can infer that the HeLa cells possess an inherent capacity to synthesize ferritin; that this capacity has been retained after many years of cell division *in vitro*, and that therefore it is connected in some way with the cell genome. Further experiments are in progress to determine whether the primary effect of iron is intranuclear or intracytoplasmic, and to learn more about the mechanisms of the phenomena reported.

It is evident that the methods described here are applicable to controlled studies of protein synthesis in relation to the fine structure of cells, to their chemical constitution, and to their function. The methods are also relevant to investigations of immune mechanisms in which ferritin can be used as antigen.

RADIATION CARCINOGENESIS AT HIGH DOSE-RESPONSE LEVELS: A HYPOTHESIS

By Prof. ARNOLD E. REIF

Biochemistry Section, Department of Surgery, Tufts University School of Medicine,
Boston City Hospital, Boston, Mass.

CARCINOGENESIS and cytotoxicity are two of the most important biological effects of ionizing radiation. The present hypothesis is an attempt to unify the concepts of their action[1]. It states that carcinogenesis and cytotoxicity act in opposition and together produce the overall relationship between radiation dose and tumour incidence that is found experimentally. The hypothesis has application to radiation therapy, and has been used to estimate the relative carcinogenic potencies of radium and strontium-90.

No assumptions are made regarding the detailed mechanism of radiation carcinogenesis, irrespective of whether in a given situation it is a primary process caused by a somatic mutation, or a secondary process caused by, for example, liberation of an oncogenic virus, or by creation of hormonal imbalance. Similarly, no assumptions are made regarding the normal defence mechanisms of the host against incipient cancer cells. Instead, consideration is confined to factual presence or absence of developing cancer cell clones. Complexities arising from the widely varying response to a carcinogenic stimulus depending on hormonal status[2] and functional integrity of the reticulo-endothelial system[3] will be discussed in a future publication.

The hypothesis assumes that the carcinogenic change is a rare but specific type of cell damage that occurs short of death of the cell. Since damage to cellular material increases as the dose of radiation is increased[4], so does carcinogenesis and the resultant incidence of tumours[5], until a maximum is reached. Beyond this maximum, the cell-killing effects of radiation would be expected to outweigh increasing carcinogenesis, resulting in a progressively lower incidence of tumours.

In fact, this expected behaviour occurs both with external radiations and with internal emitters. External cobalt-60 γ-rays given to mice in various constant daily doses resulted in a peak incidence of thymic lymphoma at 32 r./day, while at 56 r./day tumour incidence had dropped again to the level of unirradiated controls[6]. External X-rays given in a single dose to mice resulted in a peak in leukæmia incidence[7]. Injections of internal emitters such as radium, strontium-90 or calcium-45 into mice gave curves for bone tumour incidence showing sharp maxima[8]; injections of iodine-131 into rats gave similar incidence curves for thyroid tumours[5,9].

The lower portion of Fig. 1 illustrates the four main types of curves for tumour incidence found experimentally (curves *C*). While the abscissa expresses dose of a radioisotope deposited internally, curves *C* in part also represent tumour incidence induced by external radiations or by radiomimetic chemicals.

In the upper portion of Fig. 1, curve *C* has been split into two hypothetical curves *A* and *B*, which together produce *C*. Curve *A* represents 'pure' carcinogenesis, that is, carcinogenesis in the absence of other radiation effects that may counteract it. Curve *B* represents the combined cytotoxic effects of radiation on tumour cell clones, which prevent the development of all such clones in a percentage of the irradiated animals. At any dose-level, the percentage *C* of animals developing gross cancer during their life-span is the product of the percentage of animals with incipient tumour clones (*A*) and the fraction of animals in which all incipient tumour clones have not been eradicated ($1-B/100$), or:

$$C = A(1-B/100) \qquad (1)$$

Fig. 2 illustrates dissection of the cytotoxic process (curve *B* of Fig. 1) into two components, namely, eradication of tumour cells (curve *D*) and eradication of normal cells (curve *E*), which can cut short the life-span of the host before tumour clones have had time to develop into gross cancer. At any given dose-level:

$$1 - B/100 = (1 - D/100)(1 - E/100) \qquad (2)$$

The need for Fig. 2 can be eliminated by excluding animals which died from causes other than cancer during an experiment. With this correction, curve *B* in Fig. 1 is replaced by curve *D* and represents cytotoxicity against tumour.

Fig. 1 suggests explanations for the carcinogenic properties of a given external radiation, internal emitter or radiomimetic chemical[10]. Thus, production of osteogenic sarcoma in mice[8] places strontium-90 in or close to the highly carcinogenic grade 3, whereas radium falls into the medium carcinogenic grade 2. Apparently the short-range (35μ) and localized dose distribution[11] surrounding microscopic radium deposits in bone is better suited for killing any incipient cancer cells by continuing radiation than the longer range (6,000μ) and more diffuse dose distribution from strontium-90 and its daughter yttrium-09. Production of thyroid carcinomata in rats[9] classifies iodine-131 in the low carcinogenic grade 1, which differs from grade 2 in that cytotoxicity occurs at lower radiation doses than carcinogenicity. Grade 0 illustrates how a strong mutagen

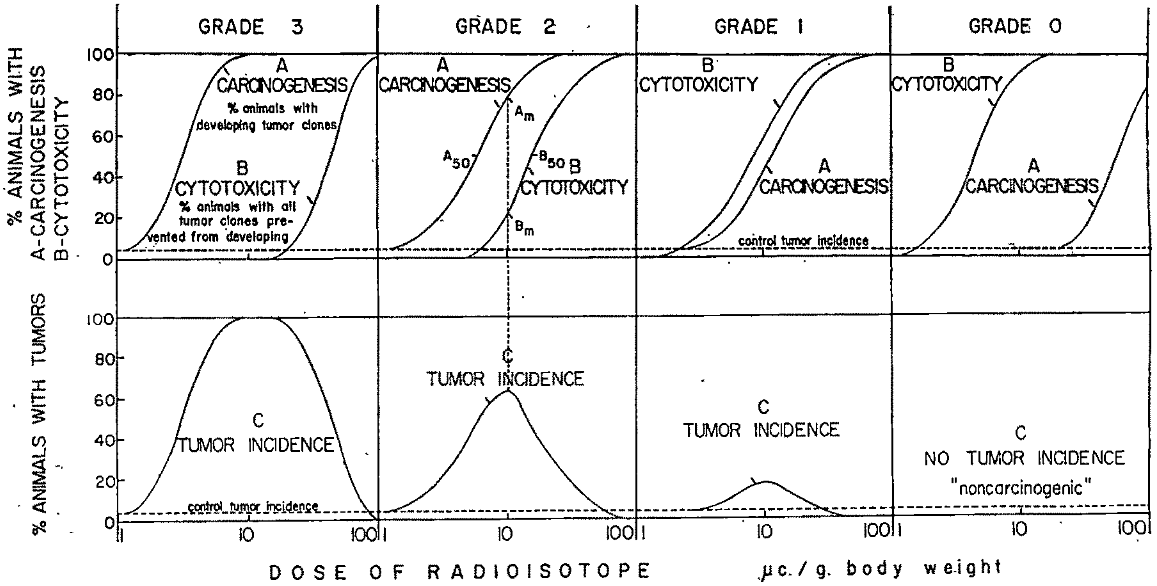

Fig. 1. Idealized curves *C*, of percentage of animals injected with a radioisotope that develop tumours, covering a range from highly carcinogenic (grade 3) to non-carcinogenic (grade 0). The overall shapes of the tumour incidence curves *C* are held to be the resultants of the opposing actions of carcinogenesis (curves *A*) and cytotoxicity (curves *B*)

such as acrolein may be non-carcinogenic[12]: cytotoxicity (in this case, acute lethality at a relatively low dose[13]) may predominate over carcinogenicity to such an extent that no gross tumours can occur. For any radiation, the carcinogenic potency evoked may depend on the mode of administration, the tissue irradiated, and the biological and genetic characteristics of the host.

Looking at Fig. 1 from the point of view of radiation therapy, the most carcinogenic dose-levels may lie just short of those giving complete cytotoxicity and therefore presenting no danger of carcinogenesis. This stresses the well-known importance of irradiating tumour masses with the highest dose-levels that can be tolerated by the patient. Irradiation of fringe areas or irradiation of normal tissues by therapeutic doses of radioisotopes should be minimized, since doses in the optimum carcinogenic range may be delivered. Because of the long latent period of radiation carcinogenesis in most body tissues, these latter considerations may apply only for younger patients.

Quantitative results are obtained by assuming that curves *A* and *B* are similar continuous *S*-shaped curves that are linear and of equal slope over their central portion. This assumption of equal slopes can be eliminated by use of equation (5) below. Curve *A* is identical with the upswing portion of curve *C* for grade 3 tumour incidence (Fig. 1), according to equation (1). While the curves for tumour incidence for strontium-90 and for calcium-45 barely miss[8,14] falling in grade 3, they do have an *S*-shaped upswing portion. For carcinogens other than ionizing radiation, grade 3 incidence curves are obtained with ultra-violet radiation[15] (which is also cytotoxic[16]) and with certain chemical carcinogens[17], and these curves are generally *S*-shaped. Similarly, curve *B* has been judged to be *S*-shaped.

At the optimum tumour dose, with tumour incidence maximal at C_m per cent, the corresponding ordinates A_m and B_m of curves *A* and *B* are related by:

$$B_m = 100 - A_m \tag{3}$$

$$A_m = 10\sqrt{C_m} \tag{4}$$

Curves *A* and *B* can be constructed graphically, provided the experimental curve *C* is known. Initially, curve *C* is drawn on semi-logarithmic paper. Next, the start of curve *A* and the end of curve *B* are traced on a second sheet, to correspond respectively with the start and with the inverted end of curve *C*. Curves *A* and *B* are continued to pass through respectively A_m and B_m, which are evaluated from equations (4) and (3). Finally, the curves are completed and if necessary replotted, such that equation (1) is satisfied by all points.

An additional refinement of questionable value is to eliminate the requirement for equal slopes of the linear portions of curves *A* and *B*. This necessitates replacement of equation (4) by the equation:

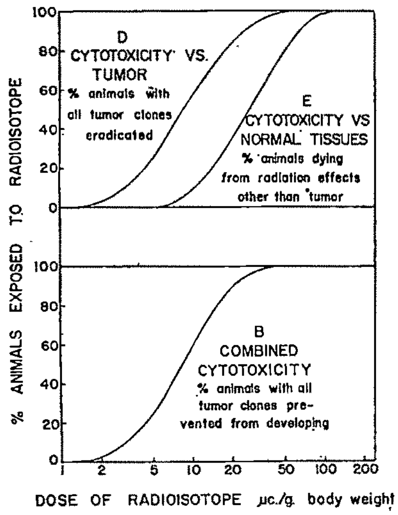

Fig. 2. Idealized curves, illustrating that overall cytotoxicity of an injected radioisotope against development of gross tumours (curve *B*) is held to be the resultant of cytotoxicity both against tumour (curve *D*) and against normal tissues (curve *E*)

$$A_m = 10\sqrt{\left(\frac{a}{b}C_m\right)} \qquad (5)$$

where a and b are the respective slopes read from curves A and B constructed using equation (4), and A_m may lie only between C_m and 100 per cent. The new values of A_m and B_m can be used to re-plot curves A and B.

Points A_{50} and B_{50} are read off curves A and B (see grade 2 curves in Fig. 1) as the LD_{50} doses for carcinogenesis and cytotoxicity, respectively. The inverse dose ratio, B_{50}/A_{50}, is a measure of potency for carcinogenesis relative to cytotoxicity, that is, of the carcinogenic–cytotoxic potency. However, the value of this quantitative result is no greater than the validity of the assumptions on which it is based.

In applying this method to Finkel's results[8,14], integral curves of type C had to be constructed from differential curves of 'tumour-rate' in the case of radium and calcium-45. Using these comparable results resulting from a single injection in mice, the approximate values of the carcinogenic–cytotoxic potencies for radium, strontium-90 and calcium-45 were respectively 1·7, 7·0 and 6·1. When more suitable experimental data are available, better estimates will be possible.

Helpful criticism from Drs. Shields Warren, Robley D. Evans and Max Ritvo, and overall support by U.S. P.H.S. grant No. *CY*-4469, are gratefully acknowledged.

EFFECTS OF GLUTAMINE AND ASPARAGINE SUPPLEMENTS IN THE DIETARY REGIMEN OF THREE PHENYLKETONURIC PATIENTS

By Dr. BARBARA H. BOWMAN* and Dr. F. J. KING†

Department of Zoology, University of Texas, Austin 12

PHENYLKETONURIA is an inherited condition which is characterized by a biochemical abnormality and usually by extreme mental retardation. The biochemical anomaly is the inability of the body to break down phenylalanine into the forms in which it can be used[1]. Instead, phenylalanine enters the blood stream in an unchanged form, most of it being converted later into phenylpyruvic acid and excreted in the urine[2].

Although many aspects of phenylketonuria are at present incompletely understood, much information has emerged from work carried on over a period of years. Through elimination of phenylalanine from the diets of phenylketonurics, abnormally high concentrations of the decomposition products of phenylalanine have been significantly lowered[3,4]. There is indirect evidence that this diminution of the decomposition products of phenylalanine is accompanied by improvement in mental function, especially in young subjects[5],[6].

The toxicity of some of the metabolites of phenylalanine has been established, but there has been no evidence that phenylalanine *per se* is toxic[7,8]. The process by which phenylalanine is converted to phenylpyruvic acid in phenylketonuria is probably that of transamination. Meister, Udenfriend, and Bessman in 1956 gave evidence of the involvement of transamination in the formation of phenylpyruvic acid when they reported the reduction of this compound in phenylketonuric subjects to whom oral doses of glutamic acid, glutamine and asparagine were administered over a period of 12 hr.[9].

The aims of the present work were to decrease the phenylpyruvic acid–phenylalanine ratio in phenylketonuric subjects through transamination by increasing the concentration of available amino donor and to study the effects of this in the phenylketonuric patients over a period of several months. Three phenylketonuric siblings were fed selected amino-acids under controlled conditions for approximately four months. A fourth affected child received a placebo. Daily urine specimens were collected from each subject for a few weeks before and during the entire period of administration of supplements. In the last weeks of the work one urine specimen was collected from each subject once a week. Urinary phenylpyruvate-levels were determined by a modification of the method of Penrose and Quastel[10]; urinary phenylalanine was determined by paper chromatography[11].

Subject I was a 21-year-old female who had an intelligence quotient (*I.Q.*) score of 18 before the amino-acid administration was begun. After the collection of daily urine specimens from her for a period of 5 weeks, she was given 3 daily doses of 7·3 gm. of L-asparagine over a period of 21 weeks, during which time daily or weekly specimens were also collected. Mental performance was tested once before and twice during the period in which L-asparagine was being given, and an increase of 9 points in *I.Q.* score was observed at the end. Although a significant decrease of phenylpyruvic acid excretion in this subject was not apparent during the treatment, there was a definite decrease in the urinary phenylpyruvic acid–phenylalanine ratio. The *t* value for the significance of the difference between pre-treatment and during treatment means was 2·75, the probability being beyond the 5 per cent level of significance (Table 1).

Table 1. RATIO OF URINARY PHENYLPYRUVIC ACID TO PHENYLALANINE

Subject	Mean before treatment	Mean during treatment	Difference between means	*t*-Ratio	Degrees of freedom	Probability
I	0·134	0·094	0·404	2·750	5*	> 0·05
II	0·151	0·113	0·179	1·409	23	< 0·05
III	0·102	0·060	0·425	4·618	24	> 0·01
IV	0·119	0·106	0·098	0·351	18	< 0·05

* Degrees of freedom reduced to adjust for lack of homogeneity of variance of the two samples.

Subject II was a 19-year-old phenylketonuric male who had an *I.Q.* score of 12 before the amino-acid administration was begun. Urine specimens were collected daily from him for a period of four weeks, after which time he was also given daily doses of 21 gm. of L-asparagine for a period of 21 weeks. During this time daily or weekly specimens were collected. There was no significant decrease in phenylpyruvic acid excretion in this subject during the treatment, nor was there any change in his mental performance or in the phenylpyruvic acid–phenylalanine ratio. Two possible reasons for the failure of the asparagine to reduce the phenylpyruvic acid–phenylalanine ratio in this subject have been postulated. First, the subject had an average urinary concentration of phenylpyruvic acid which was approximately twice that of any other subject used in this work. Secondly, the attendants were unable to give this subject L-asparagine as regularly as the supplements were given to the other subjects.

Subject III was a 17-year-old phenylketonuric female whose *I.Q.* score before treatment was 21. Daily urine specimens were collected from her 11 weeks before she began receiving 3 daily doses of 3·3 gm. of L-glutamine. She received glutamine for 17 weeks during which time daily or weekly urine specimens were collected. In this subject glutamine feeding was accompanied by a significant decrease in the phenylpyruvic acid–phenylalanine ratio and a significant decrease in phenylpyruvic acid excretion. The *t* value for the decrease in phenylpyruvic acid–phenylalanine ratio was 4·6, the probability being beyond the 1 per cent level of significance (Table 1). An increase of 8 points in *I.Q.* score was noted at the end of the experimental period.

The fourth subject served as a control. He was an 11-year-old phenylketonuric patient who had an *I.Q.* score of 15 before the administration of the placebo. Daily specimens were collected from him 4 weeks before he started receiving the placebo. There were no changes in the *I.Q.* score, the urinary phenylpyruvic acid excretion, or in the phenylpyruvic acid–phenylalanine ratio during the period of administration of the placebo.

The results of this work contribute evidence to the hypothesis that in phenylketonuria phenylalanine is converted to phenylpyruvic acid by means of a transamination process which may be reversed by increasing the available amino donor. The reduction of the phenylpyruvic acid–phenylalanine ratio was accompanied by a slight but significant improvement in each subject's ability. No increase in *I.Q.* score was seen in the two subjects who showed no reduction in the phenylpyruvic acid–phenylalanine ratio. The direct cause of the increase in *I.Q.* scores in the two phenylketonuric subjects is unknown, although the decrease of toxic products formed from phenylpyruvic acid and its derivatives may be one possible influence[12].

PHAGOCYTIC ACTIVITY OF THE RECTICULO-ENDOTHELIAL SYSTEM

Effect of *B.C.G.*

IT has been reported previously that the active œstrogens are strong stimulants of the phagocytic activity of the reticulo-endothelial system[1-4]. These results were found with both natural and synthetic œstrogens. It would appear that the configuration of the molecule, which confers œstrogenic activity, is also essential for reticulo-endothelial stimulation.

The present investigation was designed to ascertain the effect of *B.C.G.* on the phagocytic activity of the reticulo-endothelial system, to find out whether any non-œstrogenic substances also stimulated the phagocytes and to compare the results with those of other substances reported from this laboratory.

Thirty male white mice (*T.O.* Swiss strain) of 20–25 gm. body-weight were used in these experiments. Twenty mice each received one intravenous injection of 0·05 ml. of an 8-day culture of *B.C.G.* on Dubos medium. At weekly intervals, the phagocytic activity was measured in five animals by the rate of disappearance of a known amount of specially prepared carbon from the circulating blood[5], the procedure used being that described in previous communications[1] and the total body phagocytic activity or phagocytic index being denoted by the symbol *K*. In all cases, after the assessment of phagocytic activity, blood-counts were made and the animals were then killed and the weights of the liver and spleen determined.

Ten of the animals were used as controls and showed a phagocytic index or *K*-value of 16 ± 3·8.

The results are shown in Table 1. It will be noted that at the end of one week there is a slight increase in phagocytic activity. This increase is more marked at the end of the second week and reaches a peak at the end of the third week, when the *K*-value is 78 ± 34. Thereafter the phagocytic index commences to fall and, at the end of the fourth week, the *K*-value is 39 ± 21. The stimulation of phagocytic activity is accompanied by a corresponding enlargement of the liver and spleen, which is most marked at the end of the third week, when the *K*-value is highest and is due to hypertrophy of hepatic and splenic tissue.

Table 1. EFFECT OF *B.C.G.* ON THE PHAGOCYTIC ACTIVITY OF THE RETICULO-ENDOTHELIAL SYSTEM

Duration of treatment	Phagocytic index (*K*-value)	Weight of liver (gm.)	Weight of spleen (gm.)
1 wk.	22 ± 3·6	1·12 ± 0·10	0·09 ± 0·03
2 wk.	41 ± 20	1·37 ± 0·26	0·13 ± 0·03
3 wk.	78 ± 34	1·67 ± 0·19	0·23 ± 0·05
4 wk.	39 ± 21	1·52 ± 0·14	0·17 ± 0·06
Controls	16 ± 3·8	1·20 ± 0·09	0·06 ± 0·01

The total red-cell counts indicated a slight reduction in the number of red cells, but the total white-cell counts remained normal throughout the four weeks of treatment.

The above results are in general agreement with those of Biozzi *et al.*[6,7] and show that the reticulo-endothelial phagocytes can be stimulated by non-œstrogenic substances. It has also been shown by Böhme and Bouvier[8] that killed *M. tuberculosis* strain *B.C.G.* and some of its constituents stimulate the reticulo-endothelial system and fail to induce changes in the percentage distribution of leucocytes in the peripheral circulation.

Effect of Tri-*p*-anisylchloroethylene, Dienœstrol and Stilbœstrol Diphosphate

IN the case of diethylstilbœstrol, it was shown that the minimum dose required to stimulate the reticulo-endothelial phagocytes is about one hundred times greater than the œstrogenic potential of the substance[2], and that when treatment with diethylstilbœstrol is stopped the phagocytic activity returns to normal level in about 8 days[9]. Other workers, Biozzi *et al.*[10] and Heller *et al.*[11], have confirmed our findings of reticulo-endothelial stimulation by œstrogens.

This communication deals with the effect of tri-*p*-anisylchloroethylene, dienœstrol and stilbœstrol diphosphate on the phagocytic activity of the reticulo-endothelial system and on the blood.

Fifty male white mice (*T.O.* Swiss strain) of 20–25 gm. body-weight were used in these investigations. Groups of five animals were used for testing the various compounds. In the case of tri-*p*-anisylchloroethylene, five animals received one daily-dose of 0·5 mgm. in 0·05 ml. arachis oil subcutaneously for 6 days; five received 1 mgm. in olive oil orally for 6 days and five received a similar dose orally for 12 days. The dienœstrol-treated animals each received one daily dose of 0·5 mgm. in 0·05 ml. arachis oil subcutaneously for 6 days; and those treated with stilbœstrol diphosphate each received one daily dose of 0·5 mgm. in 0·05 ml. water subcutaneously for 6 days. Two days after each course of treatment was completed, the phagocytic activity was measured by the rate of disappearance of a known amount of carbon from the circulating blood[5], the procedure used being that described in refs. 1 and 3, and the total body phagocytic activity or total phagocytic index being denoted by the symbol *K*.

The liver and spleen are known to be the principal reticulo-endothelial organs involved in removing particulate matter from the bloodstream, and, using the combined weights of liver and spleen, Benacerraf *et al.*[12] have applied a corrective factor to the total phagocytic index to give a measure of the phagocytic activity per unit of reticulo-endothelial tissue. This has been called the unit phagocytic index, and has been found to vary for a given dose of carbon according to the following equation:

$$\text{unit phagocytic index} = \frac{\text{total body-weight of animal}}{\text{combined weights of liver and spleen}}\sqrt[3]{K}$$

Generally, when the total phagocytic index *K* is raised, the unit phagocytic index rises also, indicating increased phagocytic activity per unit of reticulo-endothelial tissue.

All the animals used in the present experiments remained in good health during the course of treatment.

Twenty of the animals were used as controls. One group of ten each received 0·05 ml. arachis oil subcutaneously once daily for 6 days, the total phagocytic index *K* and the unit phagocytic index being measured on the eighth day by the carbon method referred to above.

In all the animals after the assessment of phagocytic activity blood counts were made, and the animals were then killed and the weights of the liver and spleen determined.

The results are shown in Table 2, in which, for comparison, the effect of diethylstilbœstrol on the phagocytic activity of the reticulo-endothelial system is also included. It can be seen that all the substances examined are active stimulants of both total and unit phagocytic activity, and that when treatment with tri-*p*-anisylchloroethylene and diethylstilbœstrol was continued for 12 days, the total and unit phagocytic indexes remained high in both cases. The results also show that phagocytic stimulation is accompanied by a corresponding enlargement of the liver in the case of dienœstrol, stilbœstrol diphosphate and diethylstilbœstrol, which is usual with most active œstrogens, but no hepatic enlargement was found in the animals treated with tri-*p*-anisylchloroethylene.

None of the four compounds produced any change in the blood picture, since in all the animals the total

Table 2. EFFECT OF TRI-*p*-ANISYLCHLOROETHYLENE, DIENŒSTROL AND STILBŒSTROL DIPHOSPHATE ON THE PHAGOCYTIC ACTIVITY OF THE RETICULO-ENDOTHELIAL SYSTEM

Compound used	Daily dose	Total phagocytic index (*K*-value)	Unit phagocytic index	Weight of liver (gm.)	Weight of spleen (gm.)
Tri-*p*-anisylchloroethylene	0·5 mgm. in arachis oil subcutaneously for 6 days	54 ± 25	51 ± 8	1·11 ± 0·10	0·13 ± 0·02
	1·0 mgm. in olive oil orally for 6 days	83 ± 31	67 ± 5	1·21 ± 0·13	0·05 ± 0·01
	1·0 mgm. in olive oil orally for 12 days	87 ± 27	66 ± 6	1·18 ± 0·09	0·10 ± 0·01
Dienœstrol	0·5 mgm. in arachis oil subcutaneously for 6 days	40 ± 12	45 ± 5	1·47 ± 0·09	0·13 ± 0·01
Stilbœstrol diphosphate	0·5 mgm. in water subcutaneously for 6 days	40 ± 4	48 ± 4	1·49 ± 0·19	0·13 ± 0·04
Diethylstilbœstrol	0·5 mgm. in arachis oil subcutaneously for 6 days	65 ± 12	45 ± 6	1·79 ± 0·2	0·11 ± 0·02
	0·5 mgm. in arachis oil subcutaneously for 12 days	76 ± 14	65 ± 5	1·59 ± 0·15	0·11 ± 0·02
Untreated controls		15 ± 4	40 ± 4	1·28 ± 0·12	0·09 ± 0·02
Arachis oil controls		12 ± 3	38 ± 3	1·27 ± 0·13	0·14 ± 0·03

red-cell count and the total and differential white-cell counts remained within normal limits.

In the animals given tri-*p*-anisylchloroethylene orally, the high unit phagocytic index, without accompanying enlargement of the liver and spleen, indicates that this œstrogen has produced intense phagocytic activity. This difference in the action of tri-*p*-anisylchloroethylene may be due to the fact that, although it possesses high œstrogenicity and structurally resembles stilbœstrol, it differs significantly from the other synthetic œstrogens at present in clinical use. It is actually a pro-œstrogen which is stored in body fat, released gradually, then converted by the liver into a potent œstrogen, the result closely resembling natural œstrogen secretion.

Unpublished work in this laboratory has shown that an active œstrogen such as diethylstilbœstrol stimulates the reticulo-endothelial phagocytes and increases the amount of gamma globulin in the serum to about twice the normal level, and that this reticulo-endothelial stimulation protects animals against virulent infections. In the case of tri-*p*-anisylchloroethylene, the high total and unit phagocytic indexes found in the present research, together with the known absence of the usual œstrogenic side effects, suggest that tri-*p*-anisylchloroethylene may be the œstrogen of choice for clinical use in stimulating the reticulo-endothelial system and thus increasing the body defence against infection.

DIFFERENT PERMEABILITY OF CUTICULAR SHEATH IN NORMAL AND GUARD KERATIN FIBRES

By R. Z. DE LA BURDE*
Collagen Project, Armour and Co., Chicago

THE property of hair is largely ascribed to the keratin; a protein stabilized by extensive disulphide bridges. In addition, resistant non-keratinous constituents are distributed throughout the fibre, contributing significantly to its overall stability. Those minor components, which at present are not positively identified, can be found in each of three major regions of the hair cuticle, cortex and medulla[1]. Some unequivocal differences in composition and behaviour are known to exist among similar, as well as different, keratin structures in a single species. Even a fibre grown out of a single follicle is heterogeneous in its transverse and axial directions[2–4].

Normal and guard rabbit hairs are known to differ in their pigmentation, diameter and extent of modulation[5], but no information is available concerning their differences in composition and behaviour. The following work establishes the variations in coalescence and composition between normal and guard hairs of rabbit skins, classified organoleptically and physio-chemically to the second class. The differences in coalescence of cuticular membrane between fibres were characterized on the basis of their resistance to the penetration of aniline black and acridine orange.

---

* Present address: Deutsches Wollfurschungs Institut, Rheinisch-Westfallsche Technische Hochschule, Aachen, Germany.

In order to protect collagen from the damaging effect of components of the aniline oxidative bath, the samples were pretreated with chromium and fat solutions which introduced 11·2 per cent fat substances and 0·3 per cent chromic oxide. The ash content of the sample was 4·7 per cent and the moisture varied between 9·8 to 10·6 per cent. The hair cover was characterized by a 14·2 E.D.S. (elasticity, density, softness) value, 6·3 per cent abradability and its strength of setting in the corium was 13·2 $kgm./cm.^2$ (ref. 6). The skins were exposed to acridine orange according to the method applied by Jarrett *et al.*[7]. Aniline black was applied to the hair by briefly brushing with a freshly prepared solution containing 7·5 per cent aniline hydrochloride, 2·8 per cent potassium chlorate and 2·8 per cent copper sulphate. The skins were dried for 24 hr. at approximately 45° C. with the initial relative humidity of 65 per cent and an air velocity of 0·5 m./sec. The skins were tumbled in sawdust and combed thoroughly in order to remove aniline oxidation products absorbed on the cuticle. The procedure was repeated 1–4 times. After each operation, 0·5 $cm.^2$ samples were cut from the corium side and used for the cross-sectional examination of the hair cover. The entire amount of hair from each sample was wrapped into a compact bundle, with a thread wound in a tight spiral form. The tight bundle was immersed into acetone–celluloid glue, freed of its excess, dried and cross-sectioned with a Hardy microtome. In order to prevent distortion of the fibres, the specimens were covered with cedar oil and then examined in a drop of glycerine under the microscope. For each sample the ratio of normal to guard hair resisting the formation of nigro- and pernigro-aniline in the cortex was determined. The samples treated with acridine orange were examined in a similar manner by fluorescence microscopy for the presence of red fluorescence in the medulla of the fibres.

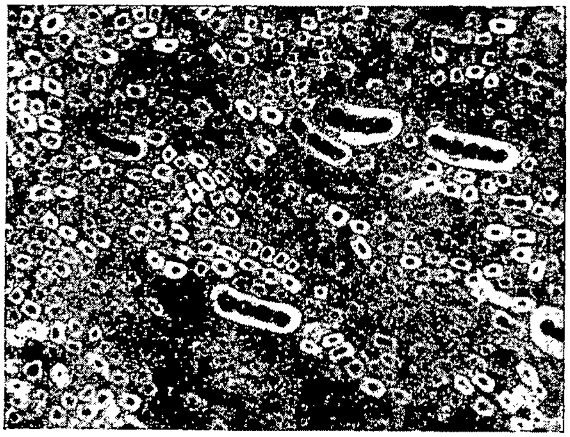

Fig. 1. Cross-section of rabbit hair bundle

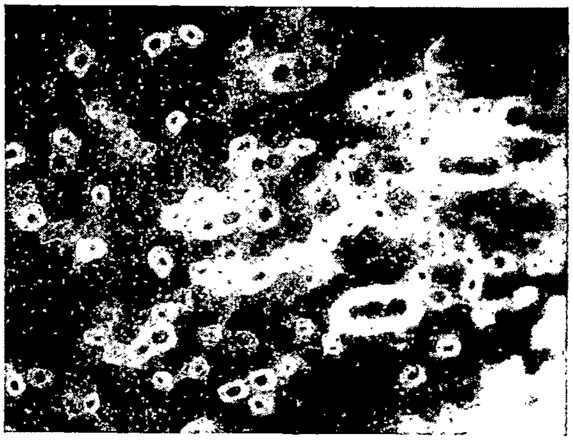

Fig. 2. Hair exposed twice to aniline black

Rabbit skins possess a great excess of normal hair (Fig. 1); its ratio to guard hair lies in the proximity of 1 : 37 bands of square and round shapes, which vary in width from $\frac{1}{8}$ to $\frac{1}{2}$ of the fibre diameter. Less than 10 per cent of total normal hair has no medulla. The guard hair is randomly distributed throughout the area of the skin. Its medullar bands vary from 2 to 8, depending on the cross-sectional region of the fibre. The ends of hair have no medulla. Microscopic examination of the dyed samples revealed that the guard hair is considerably more resistant to the penetration of acridine orange and aniline black than the normal hair (Fig. 2). The impermeable membrane in guard hair is the cuticular sheath. Wherever the cuticle was penetrated by the compound, it was found that the staining or the fluorescence was equally distributed throughout the cortex and medulla. Evidently the subcuticular resistant components which act as a cortical cell membrane[8,9] do not prevent an even distribution of the coloured compounds in this region. Neither acridine orange nor aniline black showed the differences in segmental keratinization of cortex in normal and guard hair[10].

Quantitative evaluation of the results summarized in Table 1 indicates that the cuticle of normal hair has a higher permeability to aniline than to acridine orange. The observed differences can be principally attributed to a smaller steric hindrance of the interchain bonds and non-keratinous substances towards the penetration of lower molecular weight aniline. The incorporation of fluorochrome into the medulla of normal hair is related to the number of exposures to the acridine orange. The cuticular membrane of guard hair is impermeable to this dye regardless of the number of treatments, whereas its resistance to the penetration of aniline decreases gradually.

Table 1. DIFFERENCES IN PERMEABILITY OF THE CUTICLE IN NORMAL AND GUARD HAIR

No. of exposures to dye	Ratio of resistant normal to guard hair		Total percentage of dye-permeable fibres	
	Aniline black	Acridine orange	Aniline black	Acridine orange
0	31·8 : 1	31·8 : 1	0	0
1	15·4 : 1	19·2 : 1	52·2	38·4
2	10·2 : 1	10·9 : 1	80·6	55·6
3	7·7 : 1	4·3 : 1	87·4	78·2
4	4·8 : 1	1·2 : 1	95·7	90·8
5	4·2 : 1	0·2 : 1	99·3	95·2

The rate of changes in the permeability of cuticular sheaths in normal and guard hair exposed to the aniline dye suggests that the treatment modifies progressively the protein structure. After three exposures, the ratio of both fibres resisting the distribution of nigro- and pernigro-aniline remains at the same level. Evidently some component of the dye decreases the structural resistance of the cuticular layer in guard hair to such an extent that its permeability resembles that found in normal hair. In order to establish the nature of this modification, the effect of single components on the dye permeability of guard hair was studied. It was observed that the potassium chloride and the hydrochloric acid evolved during the reaction of aniline influenced the structural resistance of the cuticle. Each pre-treatment with potassium chlorate followed by an introduction of aniline black and acridine orange changed the resistance ratio of normal to guard hair to the values corresponding to the effect of multiple dyeing listed in Table. 1. The observed effect of potassium chlorate on the cuticle of guard hair can be explained by its potential disulphide cleaving action, whereby cystine is converted to cysteic acid. It is known, however, that the action of oxidizing agents like peroxy-acids, H_2O_2, Cl and ClO_2 causes solubilization before cleavage of the disulphide bridges in keratins[11]. In the experimental conditions used in this work, potassium chlorate and hydrochloric acid did not render the protein soluble to any detectable extent. It was observed, however, that the pre-treated fibres solubilized up to 12 per cent on extraction with 0·1 *N* ammonium hydroxide.

High-temperature amino-acid analysis[12] showed that the proline and cystine contents of normal rabbit hair are 5·6 and 12·4 per cent, and in guard hair the corresponding values are 6·8 and 14·1 per cent. The results obtained for cystine were confirmed by the colorimetric method of Zahn *et al.*[13].

The observations reported here indicate that distinct differences exist in the properties of cuticular sheath of normal and guard hair grown from the topographically identical part of the corium. These differences can be explained by the varying extent of keratinization, the principal factor being the degree of disulphide cross-linkage in the cuticle of both fibres. On the other hand, the nature of the action of potassium chlorate and hydrochloric acid does not exclude the possibility that the cleavage of interchain forces occurs at sites other than disulphide bridges and possibly in the structure associated with keratin in the cuticle. It has been observed, for example, that collagen, which is not stabilized by cystine cross-linkages, diminishes rapidly during treatment with potassium chlorate, its typical properties characterized by tensile strength, maximum elongation, hydrothermal stability, etc. Comparative data on this material will be reported elsewhere later.

EFFECT OF ŒSTROGENS ON ATHEROSCLEROSIS

By Dr. M. R. MALINOW and Dr. J. A. MOGUILEVSKY
Institute of Physiology, Buenos Aires Medical School

Effect of Œstradiol on the Oxygen Consumption of Arteries in Chickens

THE oxygen uptake (Qo_2) of the uterus is enhanced in the rat by the injection of œstrogens[1] and a similar action is shared *in vitro* by endometrium, placenta, mammary gland and adenohypophysis of human origin[2]; the Qo_2 of other organs, though, may be depressed under similar experimental conditions[3-4]. Besides the well-known effects of œstrogens on genital tissues, these hormones can increase atherosclerosis of the great vessels in birds as well as inhibit and reverse coronary lesions in cholesterol-fed cockerels[5]. Since atherogenesis may be modified through a direct hormonal action on the vessels themselves[5], we decided to investigate the effects of œstrogens on the arterial oxygen uptake.

Male white Leghorn chickens raised on a standard laboratory mash and of an approximate weight of 800 gm. were killed; both innominate arterial trunks were rapidly excised and incubated separately at 37° C. on a balanced saline solution[6] also containing penicillin, streptomycin and 0·05 per cent ethanol. In another group of animals, one innominate trunk, chosen at random, was also incubated, but 2 µgm./ml. œstradiol-17β (Δ-1,3,5(10)-œstratriene, 3,17β-diol, melting point 197° C.) was added to the medium, the contralateral artery being taken as control. Oxygen uptake was determined, after incubation for 1 hr., with the usual manometric technique[7] and the results, expressed as $\mu l. O_2$/hr./mgm. of dry tissue, were compared using the *t*-test and tables of Fisher and Yates[8].

Results in Table 1 indicate that Qo_2 is similar in both innominate arterial trunks, although, as shown in Table 2, the oxygen uptake of arteries is increased by œstradiol.

Table 1. OXYGEN UPTAKE OF INNOMINATE TRUNKS IN THE CHICKEN

Artery	No. of birds	Oxygen uptake ($\mu l.\ O_2$/hr./mgm. dry tissue) (mean ± *S.E.*)
Right innominate trunk	6	2·124 ± 0·472
Left innominate trunk	6	2·137 ± 0·463

$t = 0{\cdot}019$; $P > 0{\cdot}90$

Table 2. EFFECT OF ŒSTRADIOL-17β ON OXYGEN UPTAKE OF INNOMINATE TRUNKS IN CHICKENS

Innominate trunk	No. of birds	Oxygen uptake (μl. O_2/hr./mgm. dry tissue) (mean ± *S.E.*)
Control	12	1·584 ± 0·210
Œstradiol-17β (2 μgm./ml.)	12	3·714 ± 0·534

$t = 3·769$; $P < 0·01$

Despite the fact that the present findings in connexion with the problem of atherosclerosis are of questionable significance, they indicate clearly that œstradiol is able to modify arterial metabolism through a direct action on the vessels themselves. Although results obtained *in vitro* may not be related to conditions prevailing in the living organism, it seems appropriate to mention here that local effects of œstrogens on arteries have also been demonstrated as an enhanced activity of alkaline phosphatase in incubated aortas of chickens[9] as well as in connexion with certain aspects of lipid metabolism[10].

Effect of Incubated Arteries on Œstradiol-containing Media

It has already been demonstrated[5,11,12] that œstrogens prophylactically inhibit and therapeutically reverse coronary atherosclerosis in cholesterol-fed cockerels, even in the absence of any influence on aortic atherogenesis. Intimate mechanisms involved in these effects are not known, although recent findings seem to indicate that œstrogens may modify atherogenesis through a direct action on the arteries themselves[5]. Evidence bearing on such a direct action of œstrogens on arteries includes the demonstration of radioactive material within arterial walls after the injection of tritium-labelled œstradiol-6,7 [13], enhancement of alkaline phosphomonoesterase activity in aortæ incubated with œstradiol[9] and increased oxygen uptake of arteries brought about by adding œstradiol *in vitro*. Furthermore, the well-known actions of œstrogens on blood lipids as well as on the endocrine glands, although they cannot be totally discarded in this respect, have been found not to be correlated with the arterial modifications induced by the hormones[14].

In this work, a different approach has been used in order to study the possible relationships of œstrogens and atherogenesis, namely, the determination of the endocrine activity of nutrient media where different arteries from chickens were incubated with or without œstradiol.

Fifteen white Leghorn cockerels fed on commercial mash were used. The aorta, the coronary and the carotid arteries were aseptically removed; a low-power magnifier was used to dissect the coronaries, no effort being made to free them completely from adventitial fat. In groups of 3 chickens, the coronary arteries and aortic or carotid segments of an approximate similar weight were incubated during 72 hr. at 37 ± 1° C. in modified roller tubes as described[9], using approximately 2 ml. of balanced saline medium[6] also containing 30 per cent bovine serum, 0·05 per cent ethanol, penicillin and streptomycin. Incubation was also carried out with similar media containing 2 µgm./ml. of œstradiol-17β (Δ-1,3,5(10)-œstratriene, 3,17β-diol, melting point 197° C.); the media were changed every 24 hr., pooled and kept at −20° C. until used. All media were then similarly diluted in order to attain a theoretical concentration, for those containing the hormone, of 8·33 µgm./100 ml. of medium. They were then injected into groups of 10–12 immature female Swiss albino mice, 7–12 gm. weight, according to the method of Astwood[15] modified as follows: the animals received 2 subcutaneous daily injections of 0·2 ml. during 3 days (a total theoretical dose of 0·1 µgm.), and were killed with ether 18 hr. after the last injection; the mice were then weighed, the internal genitalia dissected under a low-power magnifier (ovaries, uterus, and the vagina as reached through the abdomen) and its weight indicated per 100 gm. of body-weight. Results were compared with Student's *t*-test and its significance evaluated using the tables of Fisher and Yates[8].

The method was standardized by injecting into groups of 10 immature female mice, nutrient media containing total doses of 0, 0·05, 0·1 or 0·2 µgm. œstradiol.

As can be seen in Table 3, the weight of internal genitalia of immature female mice increased proportionally to the injected dose of œstradiol. In Table 4, it is shown that the nutrient media without œstradiol showed no activity, whereas the amount of œstrogens in hormone-containing media incubated without arteries, with the aorta or with carotid arteries, was similar to the theoretical value. The activity of hormone-containing media incubated with coronary arteries, though, was lower than that expected.

Table 3. WEIGHT OF INTERNAL GENITALIA OF IMMATURE FEMALE MICE INJECTED WITH ŒSTRADIOL

Total dose (μgm.)	No. of animals	Internal genitalia (mgm./100 gm. body-weight) (mean ± *S.E.*)
0	7	165·3 ± 10·56
0·01	8	320·3 ± 12·24
0·05	9	492·6 ± 18·85
0·1	8	546·6 ± 24·74
0·2	7	636·9 ± 56·31

The present findings indicate, consequently, that coronary arteries from chickens, when incubated with œstradiol, are able to modify the activity of the hormone in the nutrient medium. Whether this change is secondary to adsorption of the œstrogen to the vessels or to molecular inactivation has not yet been determined. It is interesting that the aorta and the carotid arteries, when similarly incubated, are not able to induce such an inactivation. It is not possible to state at the present time whether this phenomenon is related to the known action of œstrogens which prevent coronary atherosclerosis in chickens without affecting the aorta and the great vessels in these animals[5,11,12]. Nevertheless, the experiments mentioned here, together with those already reported[9,13], indicate that œstrogens may interact with the arteries themselves, and that the action in atherosclerosis may probably be related to metabolic modifications brought about within the

Table 4. WEIGHT OF INTERNAL GENITALIA OF IMMATURE FEMALE MICE INJECTED WITH NUTRIENT MEDIA FROM INCUBATED ARTERIES (MEAN ± *S.E.*)

		Internal genitalia (mgm./100 gm. body-weight)		
Description of media	No. of animals	Without œstradiol	No. of animals	Œstradiol 2 μgm./ml. (theoretical injected dose: 0·1 μgm./animal)
Without arteries	10	181·6 ± 7·10	10	526·8 ± 24·1†
Aorta	10	166·7 ± 16·7	10	636·8 ± 61·7

† $P < 0·01$ when compared, as indicated.

arterial walls. Further experiments are being completed and will be discussed in detail elsewhere.

Modification of Aortic Aerobic Metabolism in Rats by Gonadectomy

The importance of the sexual glands on the biology of normal arteries has not been studied thoroughly, although a few facts illustrate that such a relationship may exist. For example, the role of functioning gonads in human atherosclerosis is well known, men being more prone than women to coronary atherosclerosis, this difference tending to disappear after the menopause[16]. Furthermore, œstrogens are able to modify the development of atherosclerosis in several species[5], and a similar action is apparently shared by androgens in birds[17]. The following experiment demonstrates that the aerobic metabolism of the aorta is normally modified in rats through the influence of the gonadal glands.

Adult white albino male and female rats, weighing 150–250 gm., and reared on standard laboratory diet, were killed by brain concussion. The aorta was excised, freed from adventitial fat and the oxygen uptake determined during 1 hr. at 36·5° C. on pools of two arteries with the usual manometric technique[7] using a balanced saline solution[6] also containing streptomycin, penicillin and 0·05 per cent ethanol. Gonadectomy had been performed 30–40 days previously with a clean but not sterile technique under ether anæsthesia.

Table 5. AORTIC OXYGEN UPTAKE IN THE RAT

Groups	No. of determinations*	Oxygen uptake† (μl./hr./mgm. dry tissue)
Intact males	12	0·776 ± 0·055
Castrated males	6	2·546 ± 0·575
Intact females	10	0·680 ± 0·129
Spayed females	6	2·790 ± 0·294
t 1 vs. 2	11·283 $P < 0{\cdot}001$	
1 vs. 3	0·690 $P = 0{\cdot}50$	
3 vs. 4	6·677 $P < 0{\cdot}001$	
2 vs. 4	0·418 $P < 0{\cdot}70$	

* Each determination performed on pools of two animals.
† Mean ± *S.E.*

As can be seen in Table 5, the aortic oxygen uptake, which is similar in both sexes, is greatly accelerated by gonadectomy.

The mechanism through which the aerobic metabolism of the aorta is controlled has not yet been determined, although it is clear that the gonads share in this control. Current experiments performed in our laboratory indicate that it is probably mediated through a direct action of gonadal hormones on the arterial tissue. This work will be reported in detail elsewhere.

We wish to express our appreciation to Dr. B. A. Houssay and Dr. V. G. Foglia, who gave us helpful criticism.

USE OF TRANSPARENT ADHESIVE TAPE IN THE PREPARATION OF MICROSECTIONS

By D. S. GOWERS and R. E. MILLER
Research Department, Rohm and Haas, Co., Bristol, Pa.

IN 1954, Palmgren[1] described the use of cellulose adhesive tape as a means of holding together large sections of hard or brittle specimens during the cutting operation. The technique for transferring the section from the tape to a slide was rather elaborate, and in 1959 W. E. Beckel[2] proposed a much simpler method using different adhesive tapes. Scotch tape No. 810 (Minnesota Mining Co.), was used for sections to be fastened to the slide with albumen, while 'Mystik Kylon' tape No. 6400 (Mystik Tape Products Div., Englewood Co., Inc.), was used with 'Celloidin' as an adhesive. The Scotch tape No. 810 was removed in 30 min. or less by treatment with organic solvents such as furan, chloroform and xylene, and we had no difficulty in using the same technique with tape samples supplied by Dr. W. E. Beckel. No sample we were able to buy, however, had a soluble adhesive, and we were informed by the Minnesota Mining Co.[3] that only certain Canadian batches of this tape have soluble adhesive ; usually the adhesive is cross-linked and will not dissolve cleanly in any solvents. We purchased a wide variety of makes and types of adhesive tapes, and the only ones we found with soluble adhesives were 'Tuck' tapes Nos. 200 and 205, made by the Technical Tape Corp., New York 43. Only No. 200 had satisfactory tackiness. Beckel's method for Scotch tape No. 810 may be used with 'Tuck' tape, but it takes 1–10 hr. to remove the tape and adhesive with xylene, because the cellulose backing is not very permeable to the solvent ; the larger the piece of tape the longer it takes.

Previous applications of the tape method have been to whole animals, or heavily sclerotized whole insects. We have applied the method as it stands to the sectioning of textile fibres. Our real modification, however, is to mount the sections without removing them from the tape. In this way, and with a suitable embedding technique, we have been able to section textile fibres and delicate aggregates of polymer particles which are soluble in molten paraffin wax, and in the organic reagents normally used in section preparation. The unaltered method used on paraffin-embedded textile fibres gives very high quality sections down to 1μ, with rare failures.

The following is a typical example of the application of our modified technique to the sectioning of a solvent-sensitive specimen. 'Mystik Kylon' tape No. 6400 is used because of the thinness and flexibility of the backing.

Immerse the sample in polyvinylpyrrolidone solution (see 1 below) in an open dish. Put the dish in the vacuum oven at a temperature of 30–50° C. (depending on what the specimen will stand), and slowly pump down to about 28 in. mercury. Keep the oven in this condition for 2 min., and then bring it up to atmospheric pressure. Lift the sample from the solution with a spoon, taking up about 0·5 c.c. of solution, and pour the whole on to the flat surface of solidified embedding wax (see 2 below) in a Petri dish. The sample should be manipulated into the centre of a strip of the solution about 2 cm. long, and 3–5 mm. wide. Put the Petri dish in a desiccator over 50 per cent w/w sulphuric acid (about 35 per cent relative humidity), and let it stand there for three days. In this time the polyvinylpyrrolidone solution will dry down to a solid with the correct consistency for cutting. With a scalpel make two cuts in the wax, one on each side of the strip, so that the strip lifts away with a wedge of wax attached to it. After suitably trimming the length of the strip, embed it in a block of wax (see 2), and trim the block to a truncated pyramid so that the sample lies just below the upper surface.

Mount the block in the microtome, and cool it to 10–15° C. by blowing a jet of cooled air or nitrogen on it. After cutting down to the desired level, gently press a piece of 'Mystik Kylon' tape No. 6400 on to the exposed face of the specimen and cut the section rather slowly. The piece of tape will have a rectangle of wax on it, in the middle of which is a clear patch of polyvinylpyrrolidone containing the section. Trim the tape around the edges of the wax—it may now be handled with forceps and will not stick to everything that it touches.

Lay the tape on a slide with the wax side up. Put a drop of Farrants' medium (see 3 below) over the section, and drop the cover-slip into place. Stand a 10-gm. weight on the cover-slip, and put the slide into the vacuum oven at the temperature used for the impregnation with polyvinylpyrrolidone. Pump down until air bubbles begin to come out from under the cover-slip. Allow bubbling to go on for 2–3 sec., and then bring the oven rapidly to atmospheric pressure. Excess mountant is removed from the edges of the cover-slip with a wet brush, while the slide is rotated on a turntable. Bell's cement, or 'Murrayite' cement is excellent for sealing the preparation.

When fibres are to be sectioned they are treated as above, except that the polyvinylpyrrolidone embedded bundle is hung up on a wire rack and allowed to dry at 35 per cent relative humidity.

It is often possible to stain sections on the tape before mounting. Thus sections of acid ion-exchange beads may be stained with a variety of aqueous basic dyes, and basic beads may be stained with acid dyes, with little or no colour take-up by the tape. The feasibility of using any particular staining method can only be determined by trial.

If processing in aqueous solutions is not essential the equilibration time for the first embedding can be cut to one day in the open air, at any relative humidity, by impregnating with an alcoholic solution of Dow's 'Devlex *A* 515' resin (see 4 below), instead of polyvinylpyrrolidone. The oven temperature should not exceed 30° C. in this case, and a vacuum of only about 20 in. mercury is needed. The rest of the technique is as described above, except that the section is mounted in Hoyer's gum mastic medium (see 5 below).

The compositions used are as follows (all percentages are by weight):

(1) *Medium for the first embedding.* 43·5 per cent polyvinylpyrrolidone, Grade *K*-30 (av. mol. wt. 40,000) ; 13 per cent diethylene glycol as plasticizer; 43·5 per cent water. Glycerol may be substituted for diethylene glycol, but the film is more sensitive to relative humidity, and has only half the extension at break[4]. The above composition is suitable for sectioning without tape if the room humidity is between 30 and 40 per cent. For other humidities the amount of diethylene glycol may be changed, less being used for higher humidities.

(2) *Wax for the second embedding.* 48 per cent paraffin wax m.p. 58–60° C.; 50 per cent stearic acid; 1 per cent beeswax; 1 per cent carnauba wax.

This composition was found, by a factorial experiment at three levels for each component, to be suitable for direct sectioning of moderately hard materials. It has given excellent results in the above techniques. It was developed from a paraffin-stearic acid mixture, suggested by Preston[5], to give more coherent films on cutting.

(3) *Farrants' medium*[6]. 40 per cent water ; 40 per cent gum arabic; 20 per cent glycerol.

(4) *Alternative first embedding medium.* 43 per cent 'Devlex *A* 515' (a copolymer of N-vinyl-5-methyl-2-oxazolidinone and vinyl acetate, made by the Dow Chemical Co.); about 14 per cent propylene glycol as plasticizer ; 43 per cent absolute ethanol. For sectioning without tape this mixture gives a film which is very insensitive to room humidity. The following plasticizers may also be used : 8 per cent 1-3-butylene glycol, 8 per cent trimethylol ethane, or 8 per cent 1,2,6-tri-hydroxy-hexane, with 46 per cent 'Devlex *A* 515' and 46 per cent ethanol.

(5) *Hoyer's gum mastic mountant*[7]. Gum mastic dissolved in excess 95 per cent ethanol, filtered, and evaporated to the required consistency.

We wish to express our thanks to Dr. John O. VanHook, who suggested and supplied the plasticizers for the 'Devlex *A* 515' resin.

LETTERS TO THE EDITORS

GEOPHYSICS

A Twilight Method of determining the Vertical Distribution of Ozone

DETERMINATION of vertical distributions of ozone from lunar eclipse observations[1] suggests the practicability of similar ground-based optical methods, provided 'screens' more amenable to experimental control than the Moon can be used. Alternatives are noctilucent clouds, atmospheric layers, balloons, and artificial Earth satellites. Noctilucent clouds are rather rare and beyond experimental control; ionospheric layers give very limited information[2], as do other atmospheric layers such as sodium[3]. Following a suggestion by Dr. V. D. Hopper of this Department, a method analogous to the lunar eclipse method has therefore been developed in Melbourne, for initial application to ground-based filter photometric observations of balloons at twilight.

Rays from the twilight Sun pass tangentially through the ozone layer to a balloon floating above a substantial part of the atmospheric ozone. This gives a very long path-length through the atmosphere, having an effective thickness of ozone which depends critically on solar zenith angle. The effective thickness (reduced to S.T.P.) reaches about 7–10 cm. for the optimum minimum height of the rays, depending on the amount of ozone and its vertical distribution. This gives rise to absorption due to ozone, near the maximum of the Chappuis band, of 30–50 per cent.

A ground-based observer can then measure the intensity of various wave-lengths scattered to ground from the balloon. This has an advantage over lunar eclipse observations, apart from the frequency and control of occurrence, in that direct measurements can be made in the laboratory of the scattering properties of the scattering surface in the absence of an intervening atmosphere.

As the balloon is not above the whole of the atmosphere, it is necessary to modify substantially the lunar eclipse theory. Denoting the total effective thickness of ozone traversed by $X = x_a + x_b$, where x_a is the effective thickness in the path from the Sun to the balloon, and x_b that between the balloon and the ground, then it can be shown that, for two different zenith angles, with effective thicknesses of ozone of X and X', we have:

$$X' - X = (\alpha_2\lambda_1^{-4} - \alpha_1\lambda_2^{-4})^{-1}\left[\lambda_1^{-4}\log\left(\frac{I_2}{I_2'}\cdot\frac{S_2'}{S_2}\right) - \lambda_2^{-4}\log\left(\frac{I_1}{I_1'}\cdot\frac{S_1'}{S_1}\right)\right] \quad (1)$$

for wave-lengths λ_1 and λ_2 having decadic extinction coefficients α_1 and α_2, respectively, where S_i denotes the scattering factor of the balloon (assumed to be a function of wave-length and angle of scattering), and I_i is the intensity at the ground, of wave-length λ_i.

The effects of Rayleigh scattering and non-selective scattering have been eliminated, as well as the effect of differing sensitivities to wave-lengths λ_1 and λ_2. It is assumed that the incident intensities, at the top of the atmosphere, of wave-lengths λ_1 and λ_2, do not change during the course of the observations, without requiring any knowledge of their value or ratio. The elimination of non-selective scattering is based on the assumption that such scattering only occurs in the path from balloon to ground, and that it is constant. This could be invalidated by drifting dust or smoke clouds, or by observations during which the tangential rays pass through layers of non-selective absorbers, as would occur when the depression of the Sun brought the minimum height too low in the atmosphere. In general, this last consideration may well restrict the method to the determination of the vertical distribution above the troposphere.

The right-hand side of equation (1) can be determined by measurement, while the left-hand side can be obtained in terms of the vertical distribution of ozone.

Consider the atmosphere divided into layers of thickness Δh_i km., each having a reduced thickness of ozone per km. of a_i. Then, neglecting the curvature of the Earth for the path from the balloon to the observer, which is reasonable for zenith angles of the balloon of less than about 60°, we have:

$$x_b = \sec Z_b \sum_{h_i = 0}^{h_0} a_i \,.\, \Delta h_i \quad (2)$$

where Z_b is the zenith angle from the observer, of the balloon at a height h_0.

Between the Sun and the balloon the curvature of the Earth must be considered. Thus:

$$x_a = \sum_{h_i = h_{\text{min.}}}^{\infty} a_i \,.\, \Delta l_i + \sum_{h_i = h_{\text{min.}}}^{h_0} a_i \,.\, \Delta l_i \quad (3)$$

where

$$\Delta l_i = [(R + h_2)^2 - (R + h_{\text{min.}})^2]^{1/2} - [(R + h_1)^2 - (R + h_{\text{min.}})^2]^{1/2} \quad (4)$$

R is the radius of the Earth, $h_{\text{min.}}$ is the minimum height of the tangential ray, and h_1 and h_2 are the lower and upper boundaries of the layers considered.

X may therefore be evaluated, for a given set of atmospheric layers, in terms of a linear sum of multiples of the unknown concentrations a_i, where $R + h_{\text{min.}} = (R + h_0) \sin Z_0$ for the Sun at a zenith angle Z_0.

For known pairs of values of h_0, Z_0, and Z_b, it is thus possible to obtain a linear equation containing the unknown concentrations in each layer considered. Hence $(n + 1)$ sets of measurements, each corresponding to a particular position of the Sun and balloon, will give n independent equations of this type, which may then be solved for the unknown concentrations in n layers to give an approximation to the vertical distribution of ozone.

Large meteorological balloons in level flight[4] at 30–40 km. altitude are to be used for the initial observations. Narrow pass-band interference filters centred on 6150 Å. and 4400 Å. have been chosen for the photometer. The choice of 6150 Å. for the wave-length absorbed by ozone is governed by the interfering bands in the visible spectrum[5,6]. Interference is considerably less than in the case discussed by Dufay[5] due to the relatively short path through the troposphere.

The main practical difficulty in this method, using ground-based observation equipment, is that of eliminating the twilight sky background, which changes in a very rapid and complex manner as the Sun sinks below the horizon. This requires that the field of view of the photometer be severely restricted by a diaphragm in the focal plane of an objective mirror or lens. Accurate tracking is necessary to keep a balloon within such a field of view. The accuracy to which the height of the balloon is determined will greatly affect the accuracy of the results. If the balloon is above the bulk of the ozone layer, the uncertainty in height can be regarded as equivalent to a corresponding margin of error in time (or solar zenith angle), since it leads to an uncertainty in the minimum height of the tangential ray.

The minimum height of the tangential ray reaches the troposphere for solar depressions of about 5° or 6°, depending on the height of the balloon. This allows only about 20–25 min. during which to take all the measurements, while the rate of change of atmospheric path makes it necessary to take the readings for a given path within about 10 sec. if an accurate distribution is to be derived.

The method outlined above has a number of limitations. It is restricted to clear sky observations. It determines the vertical distribution smoothed out over large horizontal distances, rather than the distribution above a particular geographical location. It will be largely restricted to stratospheric ozone, and to observations only twice a day (except perhaps in polar regions). Finally, it requires considerable skill and experience.

On the other hand, its great sensitivity to ozone in the upper layers of the atmosphere should enable solar and seasonal variations in the equilibrium region of the ozone layer to be studied with increased accuracy. The method may also be applied to other constituents of the upper atmosphere with comparatively little modification.

I am indebted to Drs. V. D. Hopper and J. E. Laby, and to Mr. K. B. Mather, for their advice and discussions, and to the Dunlop Rubber Co. for financial support.

Motion of Geomagnetic Field Lines

In a communication with the above title[1], I stated that trapped-particle orbits in the radiation belts follow the motion of the geomagnetic field lines. As this is incorrect, the conclusions reached in that communication cannot be applied to the behaviour of the radiation belts, and my criticism of a hypothesis put forward by Rees and Reid[2] was unfounded. A more satisfactory discussion of this hypothesis has been published by Malville[3].

PHYSICS

Mercury-206: a New Natural Radionuclide

According to Cameron's mass formula[1], the value of Q_α for lead-210 (radium D) should be 3·566 MeV., which would indicate an alpha half-life of the order of 10^{10} years and an alpha-branching of the order of 10^{-9}. The same source gives 1·361 MeV. for the Q_β of the hitherto unknown mercury-206, which is formed from lead-210 by alpha decay. From a closed cycle of reactions, the sum of Q_α for lead-210 and Q_β of mercury-206 is found to be 5·0 MeV. ; the absence of known alpha-branching in lead-210 further suggests that the Q_α for lead-210 does not appreciably exceed the value mentioned above. (This has been pointed out also by Prof. I. Perlman; private communication by Dr. K. Hyde.)

The ground-state of thallium-206 is reported to be 0^- (refs. 2 and 3), which would indicate a beta half-life of the order of one day for mercury-206 at the energy mentioned above. However, the beta decay of 4·2-min. thallium-206 (Q_β = 1·51 MeV.) exhibits a log (comparative half-life) value of 5·1, which is typical for an allowed transition; if it is assumed that this is the case for mercury-206 also, a half-life of about 10 min. is obtained. On the other hand, mercury-206 contains 126 neutrons which should increase its stability, and several attempts[4] have been made to detect it under the assumption that its half-life is relatively long.

We have detected the alpha-branching of lead-210 by rapidly separating the lead fraction from a radium D,E,F mixture. Preparations from 20–200 microcuries of lead-210 were used and the measurement was carried out in a gridded ion-chamber of the type described by Karras[5]. The measurements were begun about 7 min. after the beginning of the chemical separation and continued for about 1 hr. ; during this time the polonium activity grew from less than one c.p.m. to hundreds of counts per minute. The alpha-branching of bismuth-210 was investigated in an analogous way, with results in agreement with those of Fink and Warren[4a,b] ; results on both nuclides are given in Table 1.

Table 1

Nuclide	Half-life	Measured E_α (MeV.)	Branching
Lead-210	22 years	3·76 ± 0·06	(1·8 ± 0·5) × 10^{-8}
Bismuth-210	5 days	4·80 ± 0·05	(1·9 ± 0·4) × 10^{-6}

In order to investigate the properties of mercury-206, bismuth and polonium were first removed from a solution containing 4 millicuries of lead-210. The solution was then made 1 *N* with nitric acid, whereupon bismuth and thallium holdback carriers and about 40 μgm. of mercury carrier were added. After standing for 60–75 min. the mercury fraction was extracted with an equivalent amount of 0·005 per cent solution of dithizone in chloroform. The extract was scrubbed twice with 1 *N* nitric acid and evaporated on to a small aluminium cup which was counted with an end-window Geiger–Müller counter shielded with 20 cm. of iron.

The time needed for the separation proper was 2·5 min. ; after this period, the thallium-206 daughter was retained and grew during the evaporation and mounting, which took another 2·5 min. A beta-decay graph obtained as an average of five measurements is shown in Fig. 1 (crosses) together with a decay curve calculated using 7·5 min. and 4·2 min. for the half-lives of mercury-206 and thallium-206, and

PHYSICS D

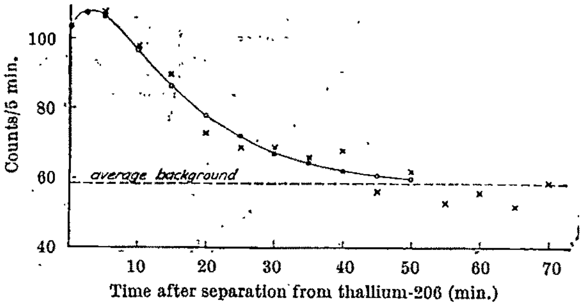

Fig. 1. Observed beta-decay of the composite mercury-206 – thallium-206 activity (crosses ; average of five measurements) compared with a decay graph calculated using 4·2 min. and 7·5 min. for the half-lives of thallium-206 and mercury-206, and assuming equal efficiencies of detection

assuming equal detection efficiencies for both activities. A value of (7·5 ± 1) min. is thus obtained for the half-life of mercury-206, while the closed cycle leads to a value of (1·2 ± 0·1) MeV. for Q_β.

We are indebted to Dr. Richard W. Fink, Dr. Goran Andersson, and Dr. Earl K. Hyde for many valuable suggestions, and to Prof. L. Simons for permission to use the equipment of the Van de Graaff Laboratory in some of the alpha-spectrometry measurements.

The investigation has been supported by the Finnish Atomic Energy Commission, the State Committee on Natural Sciences, the Chancellor of the University of Helsinki and Honkanen's Foundation.

A more detailed report of this work will be published by P. Kauranen in *Ann. Acad. Scient. Fenn.*

Note added in proof. Walen and Bastin-Scoffier (*J. Phys. Radium*, 20, 589; 1959) measured for bismuth-210 E_α = 4·686 and 4·649 MeV.; our result is clearly too high.

A Theory of Cold-Cathode Arc Movement in a Magnetic Field

WHEN a cold-cathode arc is initiated in the presence of a transverse magnetic field, movement of the cathode root occurs in a direction mutually perpendicular to the arc current axis and the magnetic field lines. At atmospheric pressure the arc moves in the amperian direction; but at low pressure, motion in the reverse sense can occur. Experimental investigations have shown that in both these modes of motion the conditions in the cathode fall region are of primary importance[1,2], and thus an understanding of the processes occurring in this region is necessary to an explanation of arc motion. A mechanism for retrograde motion at low pressure has been described by Ecker[3]; but to date no satisfactory explanation of the normal amperian motion has been put forward.

The cathode fall may conveniently be divided into three zones[3]: (1) a space-charge zone very close to the cathode surface; (2) a transition zone, where the field is less than in the space-charge zone; (3) the contraction zone, where quasi-neutrality exists. It seems probable that for the cold-cathode arc, in which current densities of the order of 10^6 amp./cm.^{2} are generally believed to exist, a field-type of emission process is operative. If either the thermal[4] or individual[5,6] field emission mechanisms are postulated, a background field $\sim 10^7$ V./cm. is likely to be necessary in the space-charge zone. As the voltage across the fall region is always about 10 V. the extent of the space-charge zone must be less than λ^+, the ion mean free-fall distance, even at atmospheric pressure, though the field in this region will decrease somewhat away from the cathode surface. The small depth of the space-charge zone can be explained by assuming a progressive back-diffusion of electrons against the electric field[3].

For convenience, calculations of electron behaviour in the fall region may be made for two different cases with the limits:

$$(a)\ R > \lambda_+ \qquad\qquad (b)\ R < \lambda_+$$

where R is the radius of an emitting area on the cathode. It can be shown that case (*a*) corresponds to the high-(atmospheric) pressure arc, while (*b*) is valid for the low-pressure arc. Only (*a*) will be discussed here since it is proposed to describe a model for amperian motion. As $R > \lambda_+$, and the extension of the space-charge zone, $d_s < \lambda_+$, a one-dimensional electric field results and electron movement in the space-charge zone will be essentially normal to the cathode surface. This is true despite the presence of the transverse magnetic field since the electric field is so large. In passing through the zone an electron will gain about 6–8 eV. energy. Current densities of about 10^6 amp./cm.^{2} have been observed for vacuum arcs as well as those operated at a pressure of several atmospheres, so that it would appear that the background field of about 10^7 V./cm. is affected little by pressure. Since also the cathode voltage remains sensibly constant at about 10 V. for a wide pressure-range, it would seem that both the energy gain in the space charge region and the depth of this region vary very little.

In the transition zone, the electrons will suffer many elastic collisions before they gain the few extra eV. required for an inelastic collision. It is almost certain that in air, which is considered here, ionization occurs by a series of electron impacts which raise the gas particle to successively higher excited levels[7], although thermal energy in this region will to some extent aid this process. In this zone the electrons, prior to excitation collisions, have a high random velocity, by virtue of their energy, but their drift velocity normal to the cathode surface is low, because of the many collisions which occur. The transverse magnetic field is thus able to deflect the electrons in the amperian direction.

By making a few simple assumptions, it can be shown that the extension of the transition zone, d_t, is given by:

$$d_t = \frac{\lambda_-}{2f^{1/2}} \cdot \tanh^{-1} \frac{2f^{1/2}}{E\lambda_-}\,(V_t - V_s) \qquad (1)$$

where λ_- is electron mean free path ; f is fraction of energy lost by electron in elastic collision ; V_t is voltage across both transition and space-charge zones ; V_s is voltage across space-charge zone only; E is field in transition zone, which is assumed approximately constant to aid calculations.

The corresponding deflexion in the amperian direction, y, for an electron moving d_t through the transition zone is given by :

$$y = B\left(\frac{e}{m}\right)^{1/2} \frac{\sqrt{2}}{3} \frac{\lambda_-}{E} (E.d_t + V_s)^{1/2} \qquad (2)$$

where B is transverse magnetic flux density; m is electron mass.

In the physical picture of the model proposed it is implicit that $(E.d_t + V_s)$ must remain approximately constant, in value equal to the first excitation potential of the gas, any variation being merely that required to compensate for variation in the energy loss in elastic collisions.

After the electrons have produced ions at the top of the transition zone by cumulative excitation, the ions drift back to the cathode and condition it so as to give rise to further emission at this new point. Thus the amperian velocity is given by $v = \frac{y}{T}$, where $T = T_1 + T_2$, T_1 being the time for the ions to move from the top of the transition zone to the cathode, and T_2 the time for emission at the new site to become 'established'. Previous experimental results[8] suggest that T_2 is generally greater than T_1. As T_2 would not be expected to vary with magnetic field strength and pressure the arc velocity should be proportional to the deflexion y. Therefore one would expect the velocity to be directly proportional to B, the magnetic flux density, as is in fact observed[8,9]. When the ambient pressure is reduced below atmospheric, Yamamura[9] finds that the velocity decreases only slowly, or not at all, until a critical value ~ 200–400 torrs is attained, following which the velocity falls rapidly to zero on further pressure reduction. Over the range of pressure where v remains almost constant it appears from equation (2) that $\frac{\lambda_-}{E}$ is approximately constant. This is not altogether surprising as the increase in λ_- with decrease of pressure causes $eE\lambda_-$ to increase compared with kT_e (k is Boltzmann's constant, T_e is electron temperature), so that back-diffusion of electrons in the transition region is checked and E correspondingly increases. The process is therefore cumulative. As $(V_s + E.d_t)$ is approximately constant, d_t decreases as E increases, so that the model progressively approaches that given by Ecker for case (*b*) at low pressure, as would be expected.

For satisfactory channelling of the ions to the cathode $eE\lambda_+ > kT_+$. At atmospheric pressure, therefore, E cannot be less than about 5×10^3 V./cm. From equation (2) the value of d_t can thus be estimated, and it may be shown that each electron makes a hundred or so collisions before having an exciting collision, at atmospheric pressure. When the number of elastic collisions per electron in the transition zone becomes small, equations (1) and (2) are no longer valid and the model breaks down. A criterion which loosely defines the point at which the model would fail is :

$$d_s + d_t \simeq \lambda_+ \qquad (3)$$

Calculations indicate that the relation (3) is satisfied at 300–400 torrs, which is the same region as experiments indicate that the velocity tends rapidly to zero.

Finally, substitution of experimental quantities in equation (2) and the use of measured velocities yield values for T. T_1 may be calculated and this shows values of T_2 which are reasonable in the light of previous observations[8]. It would therefore appear that the proposed model offers a reasonable explanation for amperian arc motion.

It is hoped to publish a more detailed account of this mechanism and confirmatory experimental data elsewhere.

We thank Prof. M. W. Humphrey Davies for his interest and encouragement, and Mr. G. E. Austen of the Electrical Research Association for his help in translating. One of us (P. E. S.) wishes to acknowledge the award of a research fellowship by the Department of Scientific and Industrial Research.

Variation with Temperature of the Photoelastic Constants of Sodium Chloride

Recently, Bhagavantam and Krishnamurty[1] investigated the variation with temperature of the stress-optical constants $(q_{11}-q_{12})$ and q_{44} of a few alkali halide crystals, using Babinet and Rayleigh compensator methods. In continuation of these investigations, we have now undertaken the study of the variation with temperature of the stress- and strain-optical constants of a number of cubic crystals in the temperature range 30–300° C., for the wavelength 5890 Å. This communication gives the outline of the method and the results obtained in the case of sodium chloride.

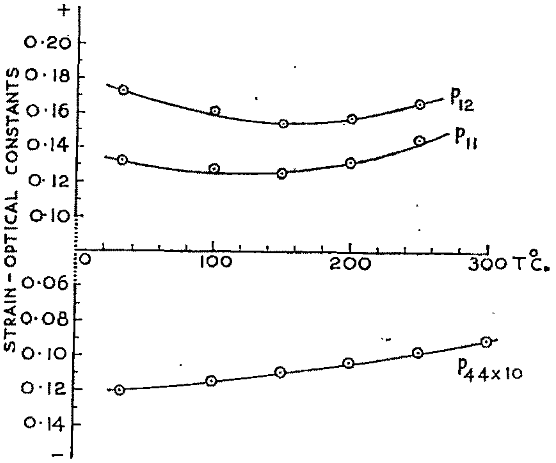

Fig. 1. Variation with temperature of the absolute strain-optical constants of sodium chloride

Table 1

Temperature (° C.)	$-(q_{11}-q_{12})$ (units of 10^{-13} C.G.S.)	$-(p_{11}-p_{12})$	p_{12}/p_{11}	p_{11}	p_{12}	$-q_{44}$ (units of 10^{-13} C.G.S.)	$-p_{44}$
32	1·12	0·041	1·31	0·132	0·172	0·94	0·0120
100	0·99	0·033	1·26	0·128	0·161	0·90	0·0113
150	0·91	0·029	1·23	0·125	0·154	0·87	0·0108
200	0·84	0·025	1·19	0·132	0·157	0·84	0·0103
250	0·78	0·022	1·15	0·145	0·167	0·80	0·0096
300	0·74	0·020	—	—	—	0·76	0·0090

A modified form of Filon's method[2], with a suitable heating arrangement, has been used to measure the stress-optical constants $(q_{11}-q_{12})$ and q_{44} at different temperatures. From these results, using the appropriate elastic constants, the strain-optical constants $(p_{11}-p_{12})$ and p_{44} are evaluated. To determine the absolute strain-optical constants p_{11} and p_{12}, the ratio p_{12}/p_{11} is measured at different temperatures by a modification of the ultrasonic method[3]. Combining the values of p_{12}/p_{11} and $(p_{11}-p_{12})$, the absolute strain-optical constants p_{11} and p_{12} have been evaluated. Table 1 shows the results obtained for sodium chloride. It was possible to measure p_{12}/p_{11} up to only 250° C., as the Hiedemann pattern became very diffuse above this temperature. The variation with temperature of p_{11}, p_{12} and p_{44} is shown graphically in Fig. 1. The elastic constants at different temperatures needed for these calculations are taken from a paper by Hunter and Siegel[4] and the thermo-optical data have been provided by M. A. H. Shareef (private communication). Work with other crystals is in progress and will be published in due course.

Intensity Aspects as Determinant of $r_e'-r_e''$ in the Bands of the Lanthanum Oxide (LaO)($B\to X$) System

An attempt made by Meggers and Wheeler[1] to investigate the rotational analysis of the yellow system of lanthanum oxide did not prove successful, because of the low resolving power of the concave grating used by them. This band system has not yet been subjected to a successful structure analysis, though some attempts are under way[2]. Tawde and Chandratreya[3] have estimated the difference (Δr_e) in the internuclear separations in the levels B and X of this system to be 0·057 Å., mainly from the study of vibrational transition probabilities in relation to asymmetry of the molecules. A later investigation[4] on the vanadium oxide (VO) (green-yellow) system has revealed the validity of revised rotational constants[5]. This was based purely on consideration of the results of the comparative study of the experimental and theoretical transition probabilities, and not on the study of the asymmetry effect on the transition probabilities made by them for the purpose. It occurred to me to establish the Δr_e-value of the yellow system of lanthanum oxide from considerations similar to those in vanadium oxide, so as to enable those engaged in the rotational analysis of this band system to use the value as a check on their determinations.

Chandratreya[6] has derived the experimental transition probabilities of this band system. They are shown in Table 1. His value of the experimental transition probability of the (0,0) band, which is the intense band of the system, is 0·79. Using this value and the mathematical technique of Manneback[7], Δr_e is calculated for the (0,0) band. It is found to be $0{\cdot}0378_2$ Å. This value was checked from two other bands (0,1) and (1,0) and is about ±0·004 Å. on either side. With this value of Δr_e, the Franck-Condon factors of the other bands have been computed and are shown in Table 1. Hutchisson's method[8] has been used to check these values[9].

Table 1

Band v', v''	Experimental	Theoretical $\Delta r_e = 0{\cdot}0378_2$ Å.	Band v', v''	Experimental	Theoretical $\Delta r_e = 0{\cdot}0378_2$ Å.
0,0	0·79	0·79	2,0	0·05	0·02
0,1	0·21	0·18	2,1	0·14	0·32
0,2	0·05	0·03	2,2	0·31	0·24
			2,3	0·40	0·28
1,0	0·16	0·19	2,4	0·08	0·11
1,1	0·57	0·46	3,1	0·07	0·04
1,2	0·31	0·26	3,2	0·26	0·39
1,3	0·05	0·07	3,3	0·27	0·11
			3,4	0·49	0·25

The molecular constants needed for this computation are taken from Herzberg's treatise[10]. As lanthanum oxide is a molecule of considerable astrophysical importance[11], these two sets of transition probabilities will be useful to the astrophysicists. It is found from Table 1 that there is a good agreement of the experimental transition probabilities with the theoretical set calculated with $\Delta r_e = 0{\cdot}0378_2$ Å., though simple harmonic oscillator wave-functions are used in the theoretical calculations. A similar investigation by Tawde and me on the vanadium oxide (green-yellow) system referred to above lends support to such a method of assigning $\Delta r_e \sim 0{\cdot}038$ Å. in the case of B- and X-levels of lanthanum oxide.

I am grateful to Prof. N. R. Tawde for suggesting the problem. I thank the Council of the National Institute of Sciences of India for the award of a post-doctoral senior research fellowship.

Two-dimensional Fourier Transform Technique for analysing Random Structures

In the course of a number of analyses of random interstratification of layers, it has been shown that a one-dimensional Fourier transform can be calculated which gives a clue to the correct sequence of layers[1,2].

This method can readily be generalized to two and three dimensions. Suppose we have scattering material, for example, in the form of layers (this is not an essential feature of the method), and that this can be stacked in two or more ways. Suppose that these manners of stacking are mixed together randomly. The result will be an X-ray diagram which consists partly of sharp spots, and partly of diffuse bands. Viewed in three dimensions, the layers will give rise to a series of regularly packed reciprocal rods. These will have a distribution of intensity along them depending on the structure of the layer, and this distribution will further be modified by the nature of the superposition of layers.

Let us consider any plane in reciprocal space, say the ($h0l$) plane, where (001) is the basal plane. The intensity function of such a partially random crystal as we are considering will have a strict periodicity in the h direction, but will be non-periodic in the l direction. It is now possible to generalize the one-dimensional Fourier transform which one of us has described[2] into a two-dimensional transform, consisting of an infinite band, periodic in the a direction, and non-repeating in the c direction. This function will have maxima at points corresponding to unit-cell repeat distances which are present in the random crystal. These unit-cell repeat distances will be shown vectorially. Furthermore, 'combination peaks' will show the degree of randomness in the mixture, as has been described for the one-dimensional case[2].

The result of this will be to give a vector diagram showing the nature of the various combinations of translations which occur. Fig. 1 shows such a diagram for random mixtures of (a) a 15 Å. spacing of $\frac{1}{6}a$ translation, and a $17\frac{1}{2}$ Å. spacing of $\frac{1}{6}a$ translation; (b) a 15 Å. spacing of $\frac{1}{3}a$ translation and a 21 Å. spacing of 0 translation.

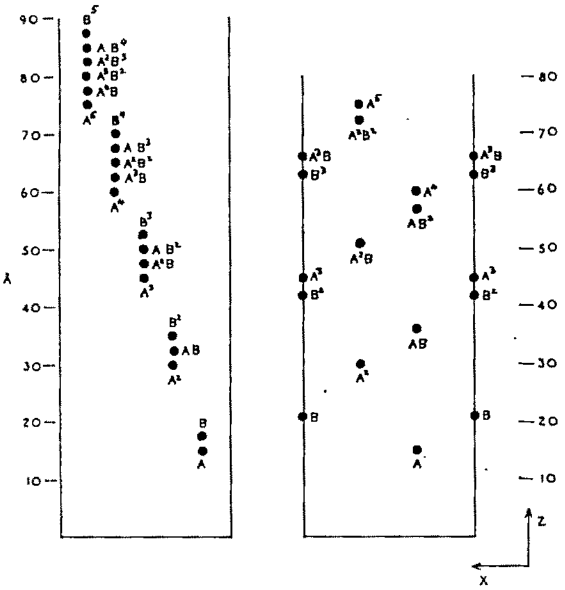

Fig. 1. Theoretical periodograms for two mixtures

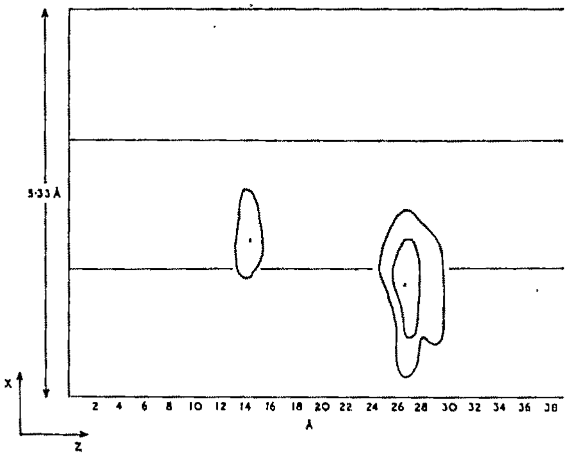

Fig. 2. A periodogram for a $C_6H_{13}NH_2$-vermiculite complex

Fig. 2 shows an actual example of a Fourier transform calculated by this method. It is for a vermiculite complexed with $C_6H_{13}NH_2$. It shows peaks at 14 Å. and 26·5 Å., both corresponding to translation of about $\frac{1}{3}a$.

In contrast to an ordinary Fourier synthesis, a diagram of this sort gives the *periodicities* associated with the crystal, and it may therefore conveniently be called a *periodogram*.

METALLURGY

Creep of Metals under Simple Shear

In a paper published last year[1], we showed with polycrystalline lead, subjected to a constant simple shear stress, that the $t^{1/3}$ law of creep held very closely within a certain range of strain, the average error being about 0·25 per cent of the range in question. We recorded, however, that for low strains, below about 0·03 with a particular lead, the law was not obeyed, the strain varying more rapidly than was indicated by the law. At high strains, too, the law fails owing to recrystallization, but to comment on that is not the object of the present communication.

Using a more sensitive recording device, we have since found that, for the lower strains in question, the strain under simple shear stress varies precisely as $t^{1/2}$. Thus with a lead for which the $t^{1/3}$ regime begins at a strain of 0·035 in the range of strain from 0·012 to 0·035, the $t^{1/2}$ law, fitted by least squares, holds with an average error of 0·25 per cent of the range, which is about the error of observation.

This $t^{1/2}$ law has been confirmed with leads differing in the small amounts of foreign metal contained, and with cadmium. For the creep under reversed stress, which can be accurately measured by the method in question, the $t^{1/2}$ law also holds within a definite range.

Mr. D. B. Gilding, working under the supervision of the senior of us with the method described in *Nature* last year[2], has confirmed the validity of the $t^{1/2}$ law over a range of small strains with lead and with cadmium.

There is evidence that at still lower strains a different power law, namely $t^{2/3}$, is valid.

Experiments are proceeding with the object of determining the glide mechanism corresponding to the different stages, so as to establish a mechanical explanation of the general creep behaviour.

Cleavage Fracture Initiation in Notched Impact Tests of Mild Steel

Many experimental observations have confirmed that brittle fracture in steel consists mainly of cleavages on the cube planes of ferrite crystals in the aggregate, with ductile fractures of the bridges formed between them. Important doubts have been expressed as to a cleavage being initiated within a crystal until the intervention of a discrete, inelastic local displacement, which might act as a trigger. Several hypotheses have arisen as to the nature of the trigger mechanism, principally involving slip and twinning. A well-known hypothesis, due to Cottrell[1], involves the intersection of two mutually perpendicular slip bands to form a strain incompatibility giving rise in turn to a void, from which cleavage may nucleate. To the best of our knowledge, the operation of this mechanism has not before been observed in steel.

Our experiments have been undertaken to explore further the nucleation of cleavage fracture in notched specimens, for which we have modified the Charpy impact test. Our objective has been to arrest the fracture as quickly as possible after initiation, in order to study the relative positions of the two fractured surfaces before they separate, using a method made known to us by Kasatkin[2]. In our development of this method, the specimen is deformed by impact at the full speed of the machine, until further bending is stopped by a surrounding rigid frame which accepts the remaining energy of the blow and transmits it to blocks of balsa wood which are permitted to be crushed. In order to secure early arrests, it has been found convenient to notch the specimens to 5 mm. depth, using a standard milling cutter of 0·25 mm. root radius, and to preform the specimens by about 2° of slowly applied bending in the reverse direction to assist crack initiation in the manner demonstrated by Mylonas[3]. We have used specimens of annealed mild-steel, bent by impact to angles between 1° and 5°, and the cracking has been observed on etched microsections taken at mid-thickness. At our testing temperature of 0° C. a completely fractured specimen of standard size shows an energy absorption of 5 ft. lb. and 95 per cent projected area of crystallinity in the fractured surface.

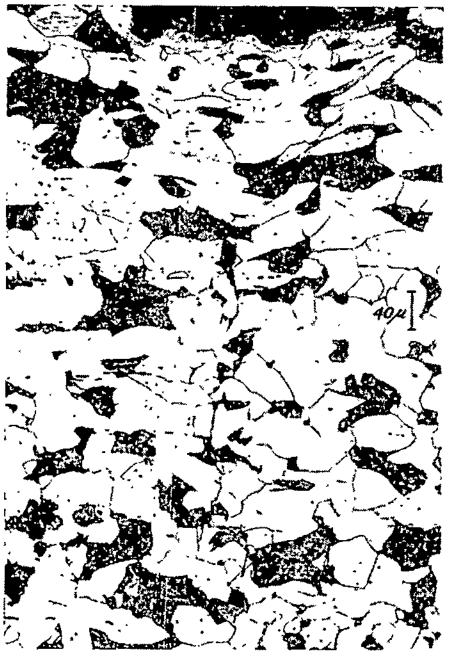

Fig. 1

The accompanying photomicrograph (Fig. 1) shows a fracture arrested at a very early stage (× 125). A significant feature is the void existing at the junction of terminating planes of heavy slip, extending from the flanks of the original notch. The cleavage fracture appears to extend from the void towards the neutral axis of the specimen, and away from the heavily deformed area. Isolated zones of twinning accompany the main cleavage fracture, but the investigation has yet contributed no evidence to distinguish their part in the process. There are isolated cleavage microcracks in advance of the main fracture front.

The initiation mechanism exposed in this specimen appears to correspond with Cottrell's hypothesis, but on a polycrystalline rather than single crystal scale.

The work is to be reported in detail soon.

CHEMICAL ENGINEERING

Polymers of Carbon Dioxide

Polymeric ions of the form $(CO_2)_2^+$, $(CO_2)_3^+$, ... $(CO_2)_{23}^+$ have been observed in the mass spectrum of carbon dioxide. These may be produced from corresponding molecules in carbon dioxide gas.

The mass spectrometer in which these ions were observed was originally built for investigating free radicals in gases at high pressures. A molecular-beam system is used for transferring the gas from a reservoir to the ion source so that reactive species are not destroyed by wall collisions. Gas molecules pass through a 0·00062-in. diameter orifice and then through a series of larger orifices which define the molecular beam and which are separated by pumping chambers. The molecular beam passes directly into the ion source where ions are formed in the usual way by electron bombardment; the spectrometer itself is a conventional magnetic sector field instrument. Further details of the apparatus are given elsewhere[1].

When carbon dioxide (commercial grade, from a cylinder), at a reservoir pressure of up to 4,000 mm. mercury and at room temperature, is examined with this system, the mass spectrum is found to contain ions corresponding with the groups $(CO_2)_n^+$. Relative intensities of ions CO_2^+, $(CO_2)_2^+ \ldots (CO_2)_{23}^+$ for a pressure of 3,800 mm. mercury (5·0 atm.) are given in Fig. 1.

Ion intensities change very rapidly with reservoir pressure, as shown in Fig. 2 for $(CO_2)_2^+$. In this case the experimental points follow the power law: $I_2 = K_2P^{2.85}$, where I_2 is the $(CO_2)_2^+$ ion intensity, P is the reservoir gas pressure, K_2 is a constant. Similar power laws are followed by ion intensities of larger polymers, namely:

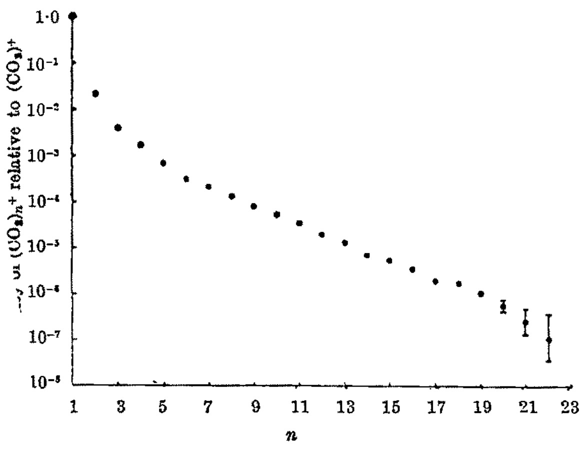
$$I_3 = K_3P^{7.8} \text{ for } (CO_2)_3^+$$
$$\text{and} \quad I_4 = K_4P^{11} \text{ for } (CO_2)_4^+$$

For the polymers larger than $(CO_2)_4^+$, the change in ion intensity with pressure is too rapid to permit even approximate measurements.

There are three possible sources for these polymeric ions: (1) They are formed in the mass spectrometer itself, either by ion-molecule reaction or some other process. (2) Polymeric molecules are formed during the expansion of the gas from the reservoir into the molecular-beam system. (3) Polymeric molecules are present in carbon dioxide gas.

The first possibility has been investigated in detail; although the evidence is not completely conclusive, it seems reasonably certain that the source of the polymers is not in the mass spectrometer. There is no evidence to indicate whether the second possibility is the cause or not; however, it seems unlikely, since an expansion involves (on average at least) the separation of adjacent molecules. Cooling of the bulk gas as a result of the Joule–Thompson effect is less than 6° C.[2] and would therefore seem to be negligible.

The third possibility, that polymeric molecules are always present in carbon dioxide, thus seems to be the most probable in the light of existing evidence.



g. 1. Measured ion intensities for polymeric ions $(CO_2)_2^+$ – $(CO_2)_{23}^+$. Reservoir pressure, 3,800 mm. mercury

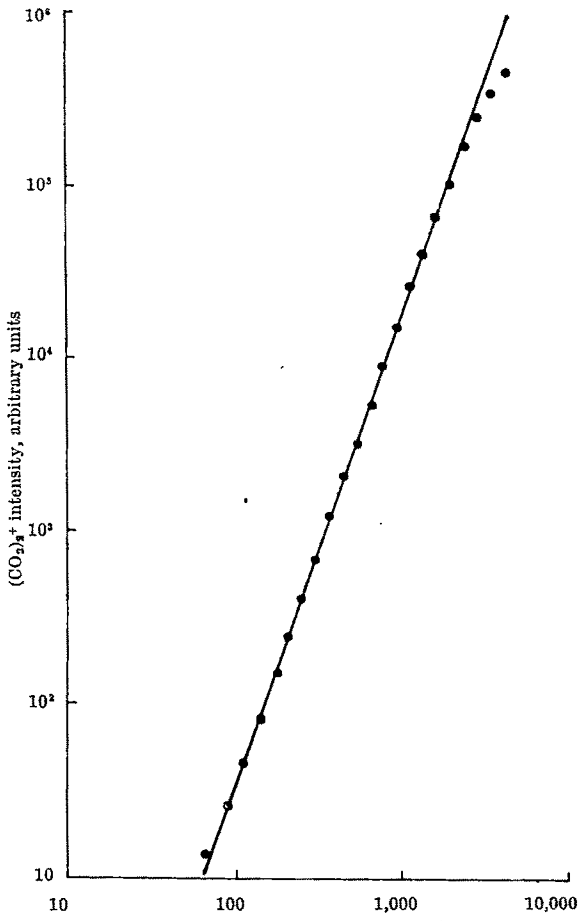


Fig. 2. Variation of $(CO_2)_2^+$ ion intensity with reservoir pressure. ●, Experimental points; —, $I_2 = K_2P^{2.85}$

Measurements at different temperatures might help in locating the source of the polymers; investigation of other gases would also be interesting.

Bubble Formation at an Orifice in a Fluidized Bed

When a gas is passed through a bed of solid particles supported by a porous distributor at a flow-rate sufficient to fluidize the bed, gas bubbles can usually be seen travelling up through the bed and breaking surface at the top. The properties of bubbles in fluidized beds have become the subject of considerable interest recently for the information

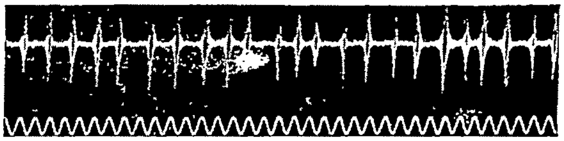

Fig. 1

their study provides on the mechanics of fluidization, and also for the part gas bubbles play in gas-solids coming into contact in fluidized beds. How gas bubbles form in fluidized beds is, however, largely unknown.

It has been shown[1,2] that the properties of gas bubbles in fluidized beds can often be described in terms of the properties of spherical-cap gas bubbles in inviscid liquids of zero surface tension[3]. The bubble and particulate (or dense) phases of a fluidized bed appear to be analogous to the gas and liquid phases in a two-phase system. A study of the formation of a gas bubble at an orifice in an inviscid liquid has recently been published[4] in which it is shown from first principles that the volume of bubble (V ml.) formed at an orifice is given by :

$$V = 1{\cdot}378\ G^{1{\cdot}2}/g^{0{\cdot}6} \qquad (1)$$

where G (ml./sec.) is a constant gas flow-rate through the orifice and g is the acceleration of gravity. In the same investigation the relationship between bubble volume and gas flow-rate through the orifice was investigated experimentally, and the results were found to be in good agreement with equation (1). Some experiments are now described in which a capacitance technique was used to determine the frequency of bubble formation at an orifice in a fluidized bed. The gas flow-rate through the orifice was known and hence the bubble volume could be calculated from the frequency. It has been found that these results may also be interpreted by equation (1), which is new evidence to support the analogy already found between two-phase systems and fluidized beds. It is hoped that these experiments will throw light on the mode of bubble formation in a fluidized bed supported by a distributor made up of orifices ; and also provide information on the initial size of a bubble in a fluidized bed.

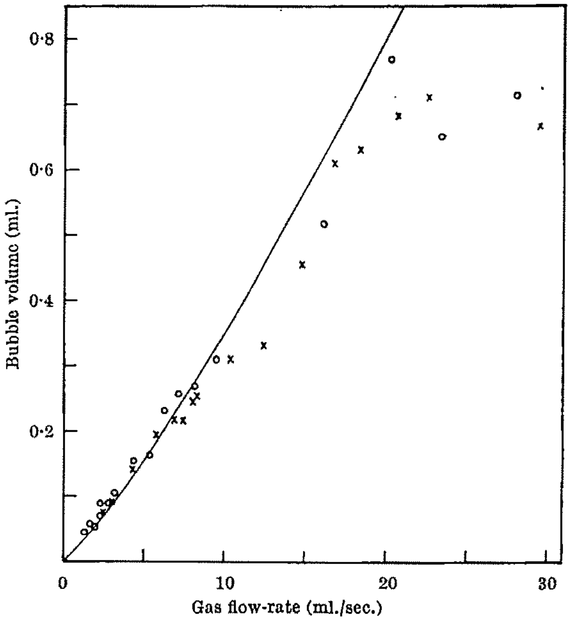

Fig. 2. Graph of bubble volume versus gas flow-rate. O, Sand in air; ×, catalyst in air; — $1{\cdot}378\ G^{1{\cdot}2}/g^{0{\cdot}6}$

The apparatus consisted of a 6-in. diameter tube in which a bed of particles was supported by a filter cloth distributor. Two sets of experiments, using sand (mean diameter 0·01 cm.) and alumina catalyst (mean diameter 0·0057 cm.), were carried out with air as the fluidizing gas. An independent stream of air at a known flow-rate was passed into the bed through a narrow injector tube, the end of which was arranged in the centre of the bed about one-third the way up from the distributor. The technique for measuring the frequency of bubble formation from the orifice at the end of the injector tube was to record the change in capacitance between a probe placed at the orifice and a probe about 3 cm. away from it in the fluidized bed. The diameters of the injector tube and the orifice were identical. A Fielden type *PM*2 proximity meter coupled to an oscilloscope was used to determine the changes in capacitance as bubbles were formed, grew, and detached from the orifice. Fig. 1 shows the output from the proximity meter for an experiment using catalyst particles, together with the 50 c./sec. trace. In this experiment the frequency of bubble formation from an orifice of 0·125 cm. diameter was approximately 32/sec. Fig. 2 shows a plot of the bubble volume against the flow-rate of air through the orifice compiled from about 30 separate experiments using either sand or catalyst particles. The complete line in the figure is a plot of the theoretical relationship between bubble volume and gas flow-rate given by equation (1). It can be seen that there is good agreement between the experimental results and the theoretical curve for flows up to about 10 ml./sec. It is noteworthy that equation (1) was also found to become inaccurate at high flow-rates in the work on air and water[4]. In the fluidized bed experiments it is considered that this inaccuracy is due in part to the formation of 'double bubbles'. Within the range of the experiments carried out so far with various sizes of orifice, the bubble frequency appears to be largely independent of bed height, the main air flow-rate to the fluidized bed, and the nature and size of the particles.

CHEMISTRY

Radiometric Precipitation in Filter Paper : Rapid Method of Micro-analysis

A radioactive material can usually be detecte and quantitatively measured by simple instrument methods at levels much below those accessible other analytical techniques. In theory, if an inact material reacts quantitatively with the active mate and the compound formed can be separated from unreacted activity, then the inactive material can be analysed at the same low levels. With th mind, several workers[1,2] have reviewed the theo radiometric analysis and considerable progres been made in its application[3-6]. In most cases, however, the difficulty of achieving clean phase separations at µgm.-levels is very great. In addition, to achieve reasonable precision and speed, it has nearly always been necessary to count the excess of unreacted activity rather than the compound formed; a procedure which reduces greatly the sensitivity of the method.

Using filter paper as a supporting medium and extending methods which have been found of value in spot tests[7,8] and paper chromatography[9,10], a rapid and simple method of micro-analysis has been developed which overcomes most of these difficulties. It consists in forming a precipitate from the active and inactive materials in the pores of filter paper and washing the paper to remove unreacted activity. The paper disk is then counted along with disks prepared in an identical manner from calibrating solutions. The method was used as follows for the determination of beryllium with a phosphate solution containing phosphorus-32.

Disks of Whatman 42 filter paper of 2 cm. diameter were numbered in pencil and arranged in rows on a glass sheet. By means of a pipette, the centre of each circle was spotted with 0·05 ml. of different beryllium solutions of known strength. After drying *in situ* at 100° C., the paper disks were transferred to about 100 ml. of 0·3 *M* diammonium hydrogen phosphate buffered at about *p*H 5·5 with sodium acetate and giving about 160,000 c.p.m. of phosphorus-32 per ml. The solution was stirred intermittently for 15 min., following which the active solution was poured off (for re-use). The paper disks were rinsed twice with demineralized water and washed for 30 min. by passing a stream of tap water into the beaker. The disks were then transferred to a large sheet of absorbent paper, dried under an infra-red lamp and counted in aluminium planchets with an end window Geiger counter. Results are given in Table 1.

Table 1

Strength of Be^{2+} solution	0·000 *N*	0·025 *N*	0·050 *N*	0·100 *N*	0·200 *N*
Counts/min./disk	72	280	549	936	1,761

These points plot to a good straight line. Good calibration plots of slightly lower precision were also obtained when 0·10 ml. or 0·01 ml. of the beryllium solutions was transferred to the filter paper instead of the 0·05 ml. used for the results quoted. The precision of a determination in the concentration-range examined would be about 2 per cent but would depend on the nature and amount of impurities and on the care taken to ensure that all the paper disks are treated in an identical manner.

The method was also applicable to the determination of magnesium by precipitation of $MgNH_4{}^{32}PO_4$ instead of $BeNH_4{}^{32}PO_4$. The interference of magnesium in the determination of beryllium could be prevented by the use of ethylenediamine tetraacetic acid in the precipitating solution. There are also indications that it will be possible to operate the method in reverse form using an isotope dilution procedure. Thus, if the centre of the paper disks is spotted with 0·05 ml. of the same inactive diammonium hydrogen phosphate solution and the disks, after drying, are transferred to beryllium solutions containing the isotope beryllium-7 at different specific activities, then the activity taken up by the paper is a reasonable function of the specific activity of the beryllium in solution provided that the total concentrations of beryllium do not vary too widely.

A method to determine chloride ion by a similar technique (by immersing the chloride-impregnated paper disks in a nitric acid solution of ${}^{110m}Ag$) gave a reasonable calibration curve when less than about 30 µgm. of Cl^- was present on the paper, but the results were anomalous at higher levels. These anomalies are thought to be due to a change in the physical form of the precipitate on the paper when certain concentration-levels are exceeded, which results in a larger fraction being removed by the standard washing technique. Further study of the factors affecting the nature of silver precipitation in filter paper will undoubtedly be very profitable since this useful isotope can form precipitates with a large number of organic compounds as well as many inorganic anions.

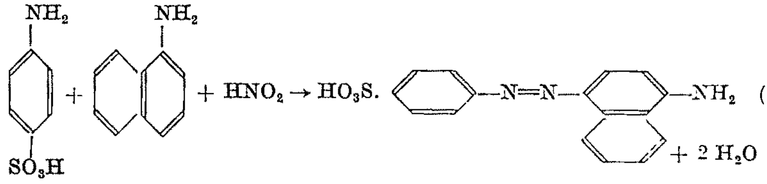
Continuous Determination of Traces of Nitric Oxide

ALL known methods[1] for the determination of traces of nitric oxide in coke oven gas and air make use of the oxidation, both by means of liquid-phase (permanganate) and gas-phase (ozone) oxidation, to nitrogen dioxide and the subsequent absorption and reaction in the Griess-Ilosvay reagent followed by colorimetric measurement of the azo dye. Calibration can be carried out using standard sodium nitrite solution and assuming the following reactions :

$$2\,NO + O_2 \rightarrow 2\,NO_2 \qquad (1)$$

$$2\,NO_2 + H_2O \rightarrow HNO_2 + HNO_3 \qquad (2)$$



(3)

It has been pointed out[1,2], however, that the analysis is affected by the non-stoichiometric character of this reaction sequence. Consequently, the reliability of the determination depends on the standardization procedure.

In order to meet the requirements for a continuous recording of traces of nitric oxide in coke oven gas and air, we have envisaged the possibility of a fast

Table 1. PHOTO-OXIDATION OF NITRIC OXIDE IN A NITROGEN–OXYGEN MIXTURE (0·3 PER CENT OXYGEN) WITH VARIABLE AMOUNTS OF 1,3-BUTADIENE
(H.P.K. mercury lamp (without filter), contact time in quartz tube 5 sec.)

1,3-Butadiene (per cent by vol.)	Nitric oxide introduced* (m.mol.)	Nitrous acid in first spiral washer with Griess-reagent (m.mol.)	Nitrous acid in second spiral washer after preceding oxidation with $KMnO_4$ (m.mol.)
0·0	$2·0 \times 10^{-4}$	$0·0 \times 10^{-4}$	—
0·001	$2·0 \times 10^{-4}$	$0·32 \times 10^{-4}$	$0·47 \times 10^{-4}$
0·01	$2·0 \times 10^{-4}$	$1·06 \times 10^{-4}$	$0·24 \times 10^{-4}$
0·05	$2·0 \times 10^{-4}$	$1·01 \times 10^{-4}$	$0·07 \times 10^{-4}$
0·1	$2·0 \times 10^{-4}$	$1·01 \times 10^{-4}$	$0·04 \times 10^{-4}$

* Concentration about 1 p.p.m.

and reliable determination which approaches as closely as possible the reaction sequence given above.

It has already been pointed out by Fullweiler[3] that the oxidation of nitric oxide to nitrogen dioxide is accelerated by dienes (an instrument based on this principle is marketed by the Rubicon Co.). However, owing to the still relatively slow rate of oxidation, this method cannot be applied for the recording of rapid changes in concentration.

We have found (patent applied for) that a fast (contact time of 5 sec.) oxidation of traces of nitric oxide can be effected by irradiation with a high-pressure mercury vapour lamp. From a preliminary investigation on the reaction mechanism it appeared that the photo-oxidation of nitric oxide occurs only in the presence of dienes. In addition it was found that with 1,3-butadiene the effective wave-length region is below 2300 Å. Therefore it seems likely that the first step in the photo-oxidation of nitric oxide comprises the formation of an excited butadiene molecule, which persists long enough[4] to react with oxygen to a peroxide.

The latter may undergo reaction, through a chain mechanism[5], with nitric oxide and oxygen to nitrogen dioxide:

$$\begin{aligned} &D\ \text{(diene)} + h\nu \rightarrow D^* \\ &D^* + O_2 \rightarrow DO_2 && (4) \\ &DO_2 + 2\,(NO) \rightarrow DO_2\,(NO)_2 && (5) \\ &DO_2\,(NO)_2 + O_2 \rightarrow DO_2 + 2\,NO_2 && (6) \end{aligned}$$

Thus, as a result of the formation of an excited diene molecule, the normal induction period of the oxidation of nitric oxide is decreased appreciably.

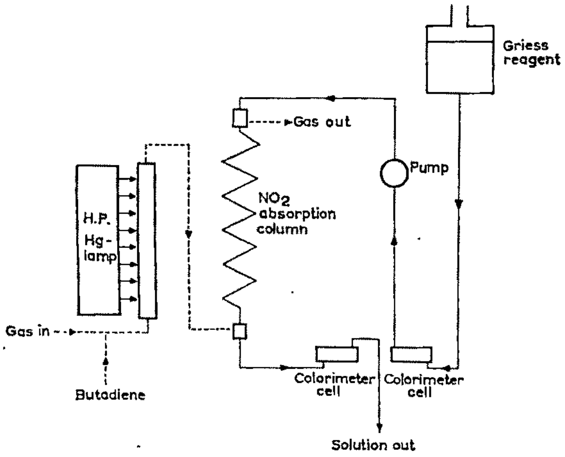


Fig. 1. Schematic diagram of nitric oxide recorder

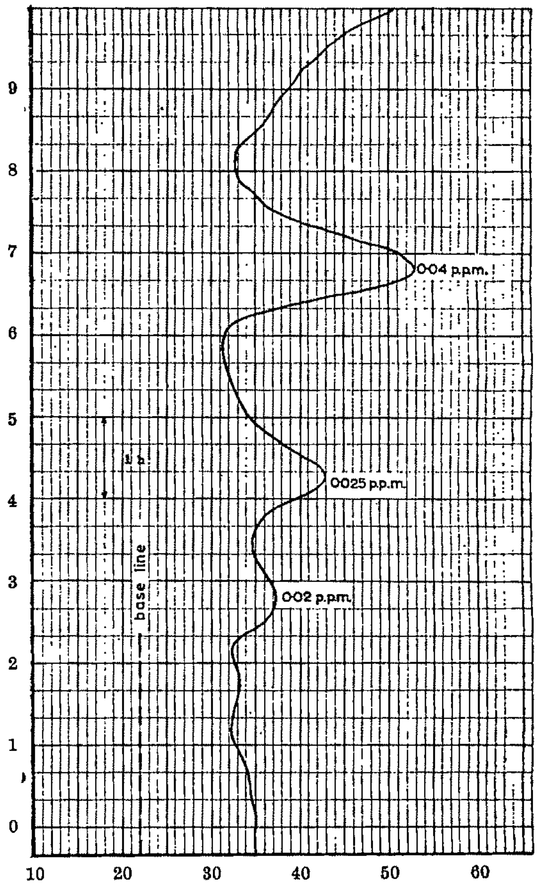

Fig. 2. Record of concentration of nitric oxide in coke oven gas (8 scale divisions = 0·01 p.p.m. oxide)

Some results of the oxidation of nitric oxide in a nitrogen–oxygen mixture with variable amounts of 1,3-butadiene are given in Table 1.

It appears that for butadiene concentrations of 0·05 per cent and higher the stoichiometry of equations 1–3 is satisfied.

A continuous nitric oxide recorder was developed based on the photo-oxidation of nitric oxide and the subsequent absorption and reaction in a spiral washer with Griess-Ilosvay reagent followed by colorimetric measurement by means of a flow type colorimeter[6]. A block diagram of the instrument is given in Fig. 1.

The nitric oxide recorder is applied for the continuous determination of nitric oxide in coke oven gas. A typical record is given in Fig. 2, in which 0·01 p.p.m. corresponds with eight scale divisions.

Finally, the method has also been applied to examination of air pollution. In this case additional 1,3-butadiene, which is already present in sufficient amount in coke oven gas, must be supplied to the air stream.

Distribution of Oxygen in a Vitrinite and its Extraction Products

A VITRINITE (petrographic purity: 99 per cent; analysis (moisture- and ash-free): 83·9 C; 5·5 H; 8·0 O; 1·4 N per cent; 1·2 per cent S by difference) was extracted with pyridine, the pyridine-soluble part with benzene, and this extract finally with petroleum ether (boiling point 40–60° C.). The ratio of material to solvent was 10 gm./litre in all cases. Each extraction was carried out in boiling solvent of analytical purity, for a period of 24 hr. with efficient stirring and under purified nitrogen. Exhaustive extraction was thus achieved at each step. A 25 per cent yield was obtained for the pyridine-soluble fraction, which could itself be extracted with benzene to the extent of 20 per cent. The petroleum ether extract represented 40 per cent of the benzene-soluble part. The former was washed further with sodium carbonate, sodium hydroxide and hydrochloric acid to yield 96 per cent of a 'neutral oil'.

The content of hydroxyl groups in vitrinite and its extraction products was determined as described previously[1], with the exception of the benzene-soluble fraction and those derived from it, in which it was better to use a method developed for asphaltic bitumens[2]. The amount of quinone oxygen was measured in the pyridine-soluble and derived fractions by means of an analytical adaptation[3] of quinone reduction with copper and hydrogen sulphide[4].

The results are summarized in Table 1. The first column gives the content of oxygen, determined moisture- and ash-free. In the petroleum ether-soluble fraction and the 'neutral oil' there is no ash, but an accurate determination of moisture according to the standard methods used for coal products was not possible on account of the relative volatility of the samples. Therefore, in these cases the analytical data for total oxygen must be considered as maximum values. In the second column (percentage hydroxyl oxygen) the small value reported for the petroleum ether-soluble fraction could not be determined with accuracy, but is certainly correct as an order of magnitude, as can also be ascertained from the near infra-red absorption at about 1·42μ. From the third column (percentage quinone oxygen), it can be seen that the benzene-insoluble fraction is the last in the series to contain quinone oxygen in detectable quantity.

Taking into account that in bituminous coals oxygen is present essentially in the form of hydroxyl groups, quinones, and as 'non-reactive'[5], the results in column 4 show that 'non-reactive' oxygen, calculated by the difference, $O_{\text{total}} - (O_{\text{OH}} + O_{\text{quin.}})$, has a remarkably constant value, of about 2·8 per cent, in all fractions where it follows directly from experimental results. Assuming that this value holds true also for the pyridine-insoluble fraction and for vitrinite itself, their quinone oxygen content can be estimated (see Table 1, column 3, results in square brackets). Considering the experimental errors made, the results obtained fit fairly well in the whole scheme for oxygen distribution in the various fractions.

Table 1. DISTRIBUTION OF OXYGEN IN A VITRINITE (83·9 PER CENT CARBON) AND ITS EXTRACTION PRODUCTS

Sample	Percentage oxygen (moist.-,ash -free)	Percentage hydroxyl oxygen	Percentage quinone oxygen	Percentage non-reactive oxygen (by difference)
Vitrinite	8·0	4·2	[1·0]	[2·8]
Pyridine-insoluble	9·0	4·5	[1·7]	[2·8]
Pyridine-soluble	7·2	3·3	1·0–1·2	2·9–2·7
Benzene-insoluble	8·5	3·7	1·6–1·8	2·8–3·0
Benzene-soluble	4·4	1·8	—	2·6
Petroleum ether-insoluble	5·3	2·5	—	2·8
Petroleum ether-soluble	max. 3·1	(0·5)	—	(2·6)
'Neutral oil'	max. 3·1	—	—	3·1

Trends observed in Table 1 are significant. In each extraction step a disproportionation of hydroxyl groups occurs which favours the insoluble residue. This concentration of polar groups is even more marked with respect to quinones. The above observations can certainly be correlated with the change of polarizability in the solvent series. Further, it may be noted that the ratio of hydroxyl to total oxygen remains remarkably constant down to the petroleum ether-insoluble component. On the other hand, the 'non-reactive' oxygen behaves quite differently, since it remains practically constant in amount from the pyridine-soluble extract down to the neutral oil and should be taken into account as a structural parameter[6].

Experiments have been initiated in this laboratory to investigate the principal nature of this 'non-reactive' oxygen by chemical means. The infra-red spectrum of the neutral oil is sufficiently specific to show clearly a band at 8·35μ (1,198 cm.$^{-1}$) which can be attributed to the antisymmetrical stretching mode of a C—O—C group in which at least one of the carbon atoms is part of an aromatic ring[7]. Thus, making the assumption that the 'non-reactive' oxygen is mainly related to at least partly aromatic ether structures, it seemed worth while to attempt cleavage of these groups with sodium in liquid ammonia[8]. Results so far obtained on the petroleum-insoluble fraction, the neutral oil, and one of its chromatographic fractions (2·5 per cent oxygen) have shown that ether cleavage, indeed, occurs under the conditions of Birch reduction.

The principal change in the infra-red is a new absorption band in the 2·9μ (3,450 cm.$^{-1}$) region due to —OH stretching, accompanied by sharply reduced intensity of the 8·35μ band. After acetylation, the reduced samples show no OH absorption but intense bands at 5·69μ (1,760 cm.$^{-1}$), at 8·31μ (1,205 cm.$^{-1}$) and increased intensity at 7·26μ (1,375 cm.$^{-1}$), which leads to the conclusion that phenolic groups have been acetylated; a further proof that ether oxygen originally present was linked at least on one side to an aromatic system.

The investigation, part of which has been described here, was supported in this laboratory by the Union Carbide Corporation, New York, to which we are grateful for permission to publish the results.

Rate of Oxidation of Ferrohæmoglobin by Ferricyanide Ions

The iron atom in hæmoglobin is part of an octahedral structure with four bonds in a plane to the nitrogen atoms of the pyrrole rings, the fifth bond directly to the globin (probably through the nitrogen atom of the imidazole ring of histidine) and the sixth bond to a water molecule[1]. Recent X-ray diffraction studies have shown that the four hæm-groups are situated on the surface of the hæmoglobin in pockets formed by folds in the polypeptide chains[2]. St. George and Pauling[3] have suggested that in aqueous solutions the folds in the polypeptide chains interfere with the binding of tertiary butyl *iso*cyanide to the hæm group. In an attempt to obtain further information concerning the effect of the environment of the hæm group on the chemical properties of the iron, we have measured the rate of oxidation of ferrohæmoglobin by ferricyanide ions, and compared this rate with that of oxidation-reduction reactions between various iron compounds.

Oxyhæmoglobin was obtained from freshly drawn human blood. About 30 ml. of blood was added to an anticoagulant medium containing acid citrate and dextrose. This was then centrifuged to separate the red cells, which were washed three times with 0·85 per cent saline solution. The red cells were then hæmolysed by adding 1·2 vol. distilled water and 0·2 vol. toluene and gently shaken. The toluene layer was separated from the aqueous layer, which was then centrifuged. The oxyhæmoglobin in the aqueous layer was estimated spectrophotometrically[4]. The oxyhæmoglobin was converted to ferrohæmoglobin by repeated evacuation and equilibration with nitrogen.

The rate of the ferrohæmoglobin–ferricyanide reaction was measured using the rapid-flow apparatus which has been previously described[5]. The reaction was investigated in a phosphate buffer with a *p*H of 6·0 and an ionic strength of 0·10. There is evidence that, at this *p*H, ferricyanide ions oxidize only the hæm group and leave the globin unchanged[6]. Second-order kinetics were observed. The rate constant for the oxidation of the first hæm group was found to be $7 \cdot 0 \pm 0 \cdot 5 \times 10^4$ l. mole^{-1} sec.$^{-1}$ at 25·0° C. with the concentration of the ferrohæmoglobin solution expressed in terms of its hæm content (mol. wt. = 17,000). Attempts to study the rate of oxidation of ferrohæmoglobin by the *tris*-(2,2′-dipyridine) complexes of osmium(III) and ruthenium(III) were unsuccessful, for these oxidizing agents reacted with the globin in addition to oxidizing the hæm-groups.

The ferrohæmoglobin–ferricyanide reaction is compared with oxidation-reduction reactions between various iron compounds in Table 1. This table also includes the products of the charges of the various reactants and the standard free-energy changes of the reactions calculated from the formal oxidation potentials of the appropriate couples[7,8].

It is apparent from Table 1 that the ferrohæmoglobin–ferricyanide reaction proceeds much slower than reactions (5) and (6). This is somewhat surprising in view of the more favourable standard free-energy change of the ferrohæmoglobin–ferricyanide reaction[7,9]. Moreover, the iron atoms in ferrohæmoglobin are uncharged and unless there are high negative charges on the neighbouring groups, the work required to bring the ferricyanide ion close to an iron atom in ferrohæmoglobin will be less than that required to bring the similarly charged ions together in reactions (5) and (6). Provided we neglect any effects due to the differences in the structures and solvations of the various reactants, we may estimate a lower limit for the rate of reaction (3) from the rates of reactions (2) and (4). Assuming that the rates of reactions (2), (3) and (4) are determined solely by the amount of work required to bring the reactants together, the rate constant of reaction (3) should be somewhat larger than the geometric mean of the rate constants of (2) and (4). This estimate will be further increased if in addition we consider the relative standard free-energy changes of reactions (2), (3) and (4). These considerations lead to an estimate of about 10^6 l. mole^{-1} sec.$^{-1}$ for the lower limit of the rate constant of reaction (3). It is apparent from Table 1 that the rate constant of the ferrohæmoglobin–ferricyanide reaction is smaller than this value.

Table 1. OXIDATION-REDUCTION REACTIONS BETWEEN VARIOUS IRON COMPLEXES AT 25° C.

	Oxidizing agent[a]	Reducing agent[a]	Z_1Z_2	ΔG^0 kcal. mole^{-1}	k l. mole^{-1} sec.$^{-1}$
(1)	$Fe(H_2O)_6^{3+}$	$Fe(H_2O)_6^{2+}$	+ 6	0	4^b

The relative slowness of the ferrohæmoglobin–ferricyanide reaction may be due to a type of steric hindrance in which the polypeptide chains prevent the close approach of the ferricyanide ions to the hæm-groups. In addition any hydrophobic groups on these polypeptide chains will tend to lower the dielectric constant in the vicinity of the hæm groups[10]. This will tend to increase the free energy of activation of the ferrohæmoglobin–ferricyanide reaction by the amount of work required to bring the ferricyanide ion from an environment of higher to one of lower dielectric constant[11]. In this connexion it is important to remember that electron transfer from the hæm group to the ferricyanide ion need not occur directly, but may occur via the polypeptide chains instead.

Another possibility is that the slowness of the ferrohæmoglobin–ferricyanide reaction is due to differences in the structures and solvations of ferro- and ferrihæmoglobin. It is apparent from reactions (1) and (2) of Table 1 that the replacement of cyanide ions in the co-ordination shells of the iron ions by water molecules leads to a marked decrease in the rate of the electron transfer reaction. Such decrease is generally ascribed to the differences in the structures of the inner hydration shells of the ferrous and ferric ions and the energy required to rearrange these shells before electron transfer can occur[11]. In a similar manner, any differences in the iron–oxygen and iron–nitrogen distances in the two oxidation states as well as any differences in the configuration of the surrounding solvent molecules will tend to slow down the rate of oxidation of ferrohæmoglobin. Because of the rigidity of the porphyrin rings, such effects are more likely to be associated with differences in the binding of the imidazole groups and the water molecules co-ordinated to the iron atoms in ferro- and ferrihæmoglobin.

It is interesting to recall that in addition to being relatively resistant to oxidation to the iron(III) state, the iron(II) in ferrohæmoglobin is able to co-ordinate oxygen rapidly and reversibly. This latter property requires that at least one of the ligands attached to the iron(II) be readily replaceable by oxygen[12]. In the case of ferrohæmoglobin this function is fulfilled by the water molecule attached to the iron(II). It is thus possible that this water molecule serves the dual purpose of enabling the ferrohæmoglobin to co-ordinate oxygen molecules rapidly and reversibly, and at the same time renders it relatively resistant to attack by such oxidizing agents as ferricyanide ions.

I wish to thank Dr. Gerald M. Edelman of the Rockefeller Institute, New York, for preparing the oxyhæmoglobin samples. This work was carried out under the auspices of the U.S. Atomic Energy Commission.

Structure and Spectra of $[(\text{Phenanthroline})_2\text{Fe}(\text{CNMe})_2]^{2+}$ and $[(\text{Phenanthroline})_2\text{Fe}(\text{CN})_2\text{H}^2]^{2+}$

THE striking shift in the position of the visible absorption bands of dicyano *bis*(1 : 10 phenanthroline) iron(II) and the corresponding 2-2′-dipyridyl complex caused by the addition of acid was first noted by Schilt[1], who has since shown that these compounds react reversibly to give mono- and diprotonated ions[2]. Schilt suggested that the hydrogen is attached directly to the metal in the protonated species. A second possibility is that the protonated compounds are '*iso*cyanides'.

Treatment of the phenanthroline compound with excess methyl sulphate gave an orange water-soluble product which precipitated from aqueous solution as the perchlorate on addition of excess sodium perchlorate. Analysis showed it to be the perchlorate of the dimethyl derivative of the original complex. It evolved methyl *iso*cyanide on warming in neutral aqueous solution.

The visible absorption spectrum of this compound is strikingly similar to that of the diprotonated form of Schilt's compound in 10 *M* sulphuric acid (Fig. 1). These facts together with the observation that the spectrum of the methyl derivative is essentially unchanged in 10 *M* sulphuric acid suggest strongly that the diprotonated ion should be written as an *iso*cyanide $[(\text{phenanthroline})_2\text{Fe}(\text{C} \equiv \text{NH})_2]^{++}$ analogous to the methyl derivative $[(\text{phenanthroline})_2\text{Fe}(\text{C} \equiv \text{N}.\text{CH}_3)_2]^{++}$.

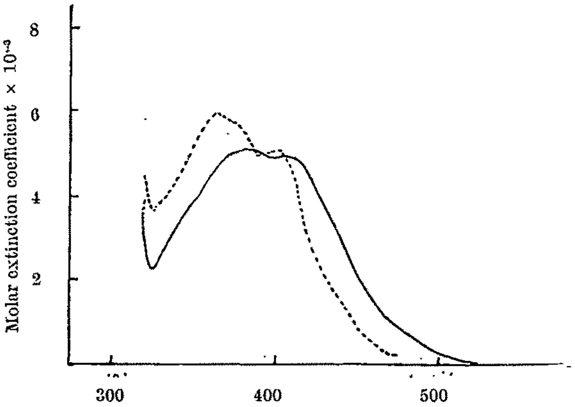

Fig. 1. Molar extinction curves for: (1) $[(\text{phenanthroline})_2\text{Fe}(\text{CNMe})_2](\text{ClO}_4)_2$ in water (—); (2) $[(\text{phenanthroline})_2\text{Fe}(\text{CN})_2]$ in 12 *M* sulphuric acid (Schilt) (...)

In an attempt to decide whether the compounds have the *cis* or *trans* configurations we have measured their infra-red spectra in 'Nujol' mulls. In each case we find evidence of a splitting of the CN frequency into two peaks separated by about 10 cm.⁻¹ (Fig. 2). This suggests, but does not prove, that the compounds have the *cis* configuration.

The intense visible absorption band of the ferrous *tris*-phenanthroline complex has often been classified as a charge-transfer band associated with the photoreduction of the organic ligand by the metal ion[1]. Since there is no permanent reaction this interpretation cannot be confirmed directly by chemical methods. Our results lend strong support to the charge-transfer hypothesis.

We may safely assume that the intense visible absorption of $[\text{Fe}(\text{phenan})_2(\text{CN})_2]$ has the same origin as that of the *tris*-phenanthroline complex. When one CN^- ion is converted to a CNH group by protonation the absorption band moves from 6000 Å. to 5000 Å.

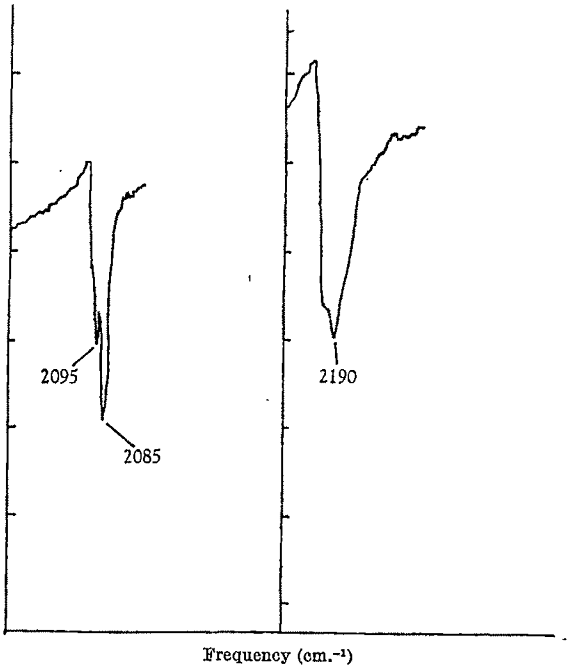

Fig. 2. Infra-red spectra of $\text{C} \equiv \text{N}$ region: (1) $[(\text{phenanthroline})_2\text{Fe}(\text{CNMe})_2](\text{ClO}_4)_2$; (2) $[(\text{phenanthroline})_2\text{Fe}(\text{CN})_2]$

When both CN⁻ groups are protonated or alkylated there is a shift of 3800 Å. We believe that the protonation (or alkylation) of the CN⁻ group transforms it from a moderate to a very strong π electron acceptor, for it is known that the *iso*nitriles resemble CO rather than CN⁻ in their ability to stabilize low valency states. The shift of the absorption spectrum is thus due to the stabilization of the ferrous state with respect to the ferric by the isonitrile group. The magnitude of the effect, about 0·6 eV. or 14 k.cal. per proton, is surprisingly large.

The visible band of the dicyanide is extremely sensitive to the nature of the solvent, moving to shorter wave-lengths as the solvent polarity is increased. This is understandable if we suppose that polar solvent molecules are strongly oriented in the neighbourhood of the cyanide groups by dipole–dipole interaction or by hydrogen bonding. Excitation leads to a quite new charge distribution in the complex which is no longer adjusted to the oriented solvent molecules. It follows that the greater the stabilization of the ion by solvent in the ground-state, the more the excitation energy is increased. Furthermore, since the nitrogen atoms of the cyanide groups lose negative charge during excitation any hydrogen bonds which they form will be weakened. These two factors account for the marked solvent effects.

Interaction of Model Peptides with Water and Lithium Bromide

Knowledge of the interactions between peptide groups and water or denaturing agents is of major importance in understanding proteins. Klotz and Franzen[1] showed recently by infra-red studies that aqueous N-methylacetamide (NMA) forms few interpeptide hydrogen bonds except at concentrations approaching 12 *M*. Hydrogen bonds between water and NMA are formed more readily. Harrington and Schellman[2] proposed that the increased viscosity of proteins in strong lithium bromide solutions is the result of more extensive bonding and more helical coiling than in water, in contrast to the widely held idea that hydrogen bonds are broken in lithium bromide solution. We present viscometric data relating to the interaction of water solutions of lithium bromide with NMA, dimethylacetamide (DMA), acetone, and polysarcosine. The results show that increased viscosities occur in systems where interpeptide hydrogen bonds cannot form.

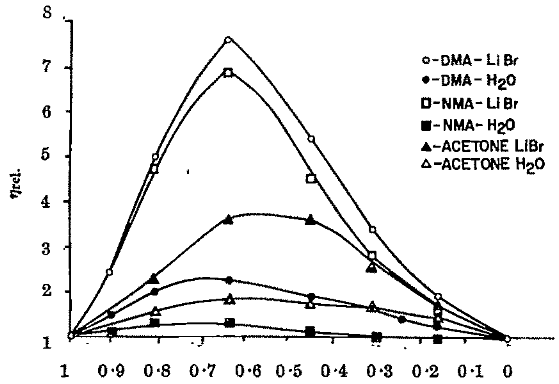

Fig. 1. Viscosities of NMA, DMA and acetone in water and lithium bromide. Solutes were mixed with water or with 10 *M* lithium bromide to obtain the volume fractions indicated

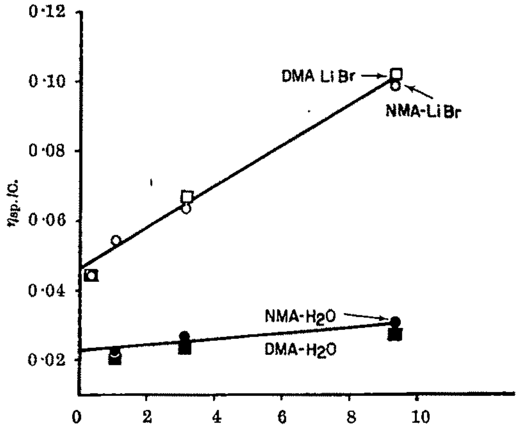

Fig. 2. Intrinsic viscosities of NMA and DMA in water and 9 *M* lithium bromide

Fig. 1 shows that mixtures of NMA, DMA or acetone with water have viscosities higher than those calculated on the assumption of ideal mixing. Mixtures of NMA, DMA or acetone with 10 *M* lithium bromide have still higher viscosities, similar to those reported for the system urea–lithium bromide[3]. The maxima of the lithium bromide curves for DMA, NMA and acetone all occur at a ratio of solute to lithium bromide of nearly 2 : 1. 10 *M* potassium thiocyanate and 9 *M* guanidinium chloride raise the viscosity of acetone or NMA one-third to one-half as much as does lithium bromide.

Fig. 2 shows that the intrinsic viscosities of NMA and DMA are higher in lithium bromide solution than in water. (All the viscosities reported here were measured in Cannon Instrument Co. dilution Ubbelohde viscometers, sizes 50 or 75, at 39° C. The flow time for NMA in the semi-micro, size 50 viscometer was 13 min. and in size 75 was 8 min. for about 1 ml. of liquid.)

In Table 1 are shown viscosities of NMA and DMA in aqueous lithium halides, hydrochloric acid, and carbon tetrachloride. Lithium chloride and bromide give similar results, so that the effect must be largely due to the lithium ion. The similarity between NMA and DMA in Figs. 1 and 2 and Table 1 show that interpeptide hydrogen bonding need not be involved in lithium bromide solutions. In carbon tetrachloride the interpeptide hydrogen bond of NMA is apparent in the elevation of viscosity.

Table 1. Relative Viscosities of Amides in Several Solvents

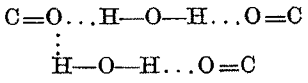
Volume and amide (ml.)		Volume and solvent (ml.)		Relative viscosity
10	NMA	1	10 *M* LiBr	2·14*
10	DMA	1	10 *M* LiBr	1·85*
10	NMA	1	10 *M* LiCl	2·32*
10	DMA	1	10 *M* LiCl	1·79*
10	NMA	1	10 *M* HCl	1·59*
10	DMA	1	10 *M* HCl	1·36*
1	NMA	9	10 *M* HCl	1·35†
1	DMA	9	10 *M* HCl	1·34†
1	NMA	9	CCl_4	1·66‡
1	DMA	9	CCl_4	1·06‡

* Relative to 10 ml. amide plus 1 ml. water.
† Relative to 9 ml. solvent plus 1 ml. water.
‡ Relative to pure carbon tetrachloride.

Of greater importance in relation to proteins is that the intrinsic viscosity of polysarcosine of molecular weight 2,500 (Schwartz Bio-Research, Inc., New York) was 0·086 in 9 *M* lithium bromide and 0·054 in *M* potassium chloride. These results for polysarcosine are contrary to those reported by Steinberg *et al.*[4] for poly-L-proline, which also cannot form interpeptide hydrogen bonds. Polysarcosine of higher molecular weight and copolymers of sarcosine and proline are being prepared for study, as are other copolymers.

$$C{=}O\ldots H{-}O{-}H\ldots O{=}C$$

(I)



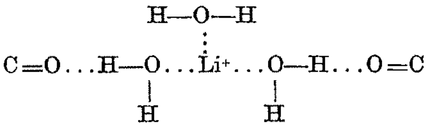
$$\begin{array}{l} C{=}O\ldots H{-}O{-}H\ldots O{=}C \\ \vdots \\ H{-}O{-}H\ldots O{=}C \end{array}$$

(II)

The high viscosities of mixture of NMA, DMA or acetone with water may be due to hydrogen bonding, as in (I) or as in (II). Two hydrogen bonds to one peptide carbonyl have been shown to exist in crystalline acetamide[5]. In the case of NMA and DMA there may also be some hydrogen bonding to the nitrogen. The low viscosity of NMA–water at high water content may result from a breaking down of the water structure. In lithium bromide solutions there may be lithium to carbonyl bonding as in (III), or bonding of carbonyl to water of the lithium hydration sphere as in (IV). The multiplicity of hydrogens in the hydration sphere of lithium would permit formation of larger aggregates than in water. At low peptide concentrations, multiple binding as in (III) or (IV) becomes less probable, and there may be only one peptide group bound for each lithium. The nature of the lithium to peptide bonding is not specified but may be similar to the ion-dipole attraction of lithium to water.

$$C{=}O\ldots Li^{+}\ldots O{=}C$$

(III)



$$\begin{array}{ccccc} & & H{-}O{-}H & & \\ & & \vdots & & \\ C{=}O\ldots H{-} & O & \ldots Li^{+}\ldots & O & {-}H\ldots O{=}C \\ & | & & | & \\ & H & & H & \end{array}$$

(IV)

Experiments were also done with 8 and 12·5 *M* lithium bromide acting on NMA. The maxima of the viscosity curves were 4·5 and 22 and occurred at ratios of amide to lithium of 3 : 1 and 1 : 1, respectively. 8, 10 and 12·5 *M* lithium bromide have water to lithium ratios of about 5, 3·7 and 3 respectively. It appears that lower hydration of lithium results in greater interaction with amides. This supports formulation (III) rather than (IV). However, lower hydrates would be expected to produce stronger hydrogen bonding as the strengthening effect of the lithium charge on the hydrogen bond would be distributed among fewer hydrogens. With 12 *M* lithium bromide the curve was not continuous, a crystalline precipitate appearing at an NMA volume fraction of 0·8. Determination of the structure of this precipitate by X-ray diffraction is planned.

In 10 *M* hydrochloric acid aggregation may be mediated by hydrogen bonding of H_3O^+ or $H_3O(H_2O)_n{}^+$ units to the carbonyl groups. Steinberg *et al.*[4] proposed protonation of peptide groups to explain the high optical rotation of poly-L-proline in strong acid.

The increased viscosity of proteins in strong lithium bromide solution may be due to extension of the polypeptide chain as a result of attaching many hydrated lithium ions in close proximity. The possibility of aggregation is also being investigated. In the case of poly-L-proline special configurational effects may be involved.

We are grateful to Dr. David Harker for suggesting hydrogen bonding of the lithium hydration sphere. This work was supported partly by a grant from the National Institutes of Health.

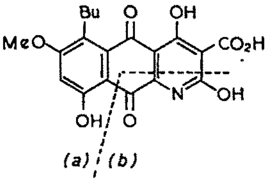
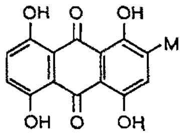
Pigments of *Phoma terrestris* Hansen and their Biosynthesis

Wright and Schofield[1] recently reported the failure of cultures of *Phoma terrestris* Hansen (from the Centralbureau voor Schimmelcultures, Baarn) to produce the pigment phomazarin[2] for which (I) is one of the two suggested structures. In our hands cultures from the same source have given this compound, which agrees well in physical properties with those described by Kögl *et al.*[2]. For reasons which we are unable to define, the same organism grown under the usual conditions[2] does not invariably produce the pigment. Like Wright and Schofield[1] we have observed cyanodontin (II) as a constituent of the mycelium.



(I)



(II)

Radioactivity from ^{14}MeCO$_2$Na and Me^{14}CO$_2$Na is incorporated into cyanodontin. The acetic acid, obtained by Kuhn–Roth oxidation of the ^{14}MeCO$_2$Na-derived material, had one-eighth of the total activity, all on the methyl group. The acetic acid obtained similarly from the Me^{14}CO$_2$Na-derived material had one-seventh of the total activity, all on the carboxyl group. This shows that cyanodontin in common with other natural 2-methylanthraquinones (for example, ref. 3) is biosynthesized through head-to-tail linkage of eight acetic acid units and loss of the carboxyl carbon from the end of the chain.

Radioactivity from H^{14}CO$_2$Na, ^{14}MeCO$_2$Na and Me^{14}CO$_2$Na is incorporated into phomazarin. Degradation has shown that about 75 per cent of the activity of the H^{14}CO$_2$Na-derived material is located on the methoxyl carbon, the remainder being randomly distributed over the carbon skeleton. Therefore the latter is formed probably without the intervention of C_1-units (cf. ref. 4). The acetic acid obtained by Kuhn–Roth oxidation and the carbon dioxide formed by decarboxylation of the $^{14}MeCO_2Na$-derived material each had approximately one-eighth of the total activity. The acetic acid obtained by Kuhn–Roth oxidation of the $Me^{14}CO_2Na$-derived material had approximately one-eighth (12·1 per cent) of the total activity, 98 per cent of it on the carboxyl group. This suggests that the biosynthesis of phomazarin involves at least eight acetic acid units and implies that the nitrogen-containing moiety may be derived from an amino-acid (cf. terramycin[5]), possibly glycine. The derivation of the carboxyl carbon from the methyl carbon of acetic acid favours a structure of type (I) over an alternative which has the terminal benzene ring inverted. If structure (I) is correct then the dotted line dissects the skeleton into portions which could be derived from (*a*) eight acetic acid units linked head-to-tail, and (*b*) glycine. Further degradations are in progress.

BIOCHEMISTRY

Amino-acid Synthesis from Hydrogen Cyanide under Possible Primitive Earth Conditions

The formation of adenine from hydrogen cyanide has been recently reported from this laboratory[1]. Continuing the work on the synthesis of biochemical compounds under possible primitive Earth conditions[2], we now have investigated the direct formation of amino-acids from hydrogen cyanide.

Gaseous hydrogen cyanide was slowly introduced into 1 litre of 3 N ammonium hydroxide placed in a 2-litre flask provided with a water-cooled condenser. At the end of 1 hr., the flow of gas was stopped and the reaction mixture was analysed for cyanide ion by the method of Schilt[3]. It was found 2·2 M in this ion.

The alkaline aqueous solution was heated at 70 ± 2° for 25 days, after which time the black polymer of hydrogen cyanide[4] was removed by centrifugation. The reddish supernatant solution was fractionated by ion exchange into two main fractions and the fraction containing the amino-acids was analysed by one- and two-dimensional paper chromatography.

For the ion exchange fractionation, 200 ml. of the supernatant were added to the top of a 4 × 40 cm. column of 'Dowex 2' resin (200–400 mesh, X 8, OH^- form). The column was first washed with water until the effluent was neutral and then the acidic and ampholytic components bound to the resin were eluted by means of 4 N acetic acid. A total volume of 1,200 ml. was collected in three sub-fractions of 400 ml. each. The first of these sub-fractions was essentially neutral and corresponded to the water hold-up volume of the column, which emerged just before the acetic acid solvent front. The second and third sub-fractions were, as expected, strongly acidic.

A preliminary paper chromatographic analysis indicated that almost all the amino-acids were present in the second sub-fraction. This solution was concentrated to dryness in a vacuum-rotating evaporator at 60°, then dissolved in 25 ml. of 1 N hydrochloric acid and analysed by paper chromatography.

For this, 25 μl. of the red-yellowish solution was placed on a small sheet of Whatman No. 3 mm. filter paper and chromatographed by ascending development, first in *n*-butanol/acetic acid/water, 4 : 1 : 1, and then, on drying, in *n*-propanol/1 N ammonium hydroxide, 3 : 1. The paper was then sprayed with 0·2 per cent ninhydrin in *n*-butanol and heated in the oven for 5 min.

Fig. 1 shows, on the right side, a two-dimensional chromatogram of the unknown; on the left side, a one-dimensional chromatogram of the standards glycine and alanine, of the unknown, and of a mixture of standards and unknown.

On the basis of this and other chromatographic evidence, the amino-acids alanine, glycine and aspartic acid, which correspond to the top three spots of the two-dimensional chromatogram, were tentatively identified among the products formed by the condensation of hydrogen cyanide in aqueous ammonia. The other spots have not yet been identified. The compound close to the origin, slowly migrating, developed maximum colour intensity only after a few days, indicating that it may be a peptide(s) or a compound of a similar behaviour to a peptide. Total amino-acids were quantitatively determined by the method of Troll and Cannan[5], and found to amount to 10 mM/l. of original reaction

mixture, measured as glycine. This represents a substantial yield if it is considered that most of the hydrogen cyanide is condensed into polymeric hydrogen cyanide[4].

When 100 µl. aliquots of the test solution were chromatographed, small spots of several other ninhydrin-positive compounds were observed. In addition, by means of a Mineralight lamp (2537 Å.) a number of ultra-violet-light absorbing and fluorescent spots were detected on two-dimensional chromatograms.

In line with the above results, Wippermann[6] and other workers[4] demonstrated many years ago the formation of glycine by mild alkaline hydrolysis of an oligomer of hydrogen cyanide which had been obtained from hydrogen cyanide by base catalysis. It is possible that the well-established tetramer of hydrogen cyanide, di-aminomaleonitrile[7], and its assumed intermediate, aminomalonitrile[8], are the precursors of the C_2-, C_3- and C_4-amino-acids obtained in the present experiments.

Work is in progress for the identification of all the amino-acids, for the elucidation of the mechanism of amino-acid synthesis, and for determination of the nature of the other compounds synthesized from hydrogen cyanide.

This work has been supported in part by research grant No. *G*-13117 from the National Science Foundation and will be reported in more detail elsewhere.

Occurrence of *n*-Odd-Numbered Monoethylenic Fatty Acids in the Liver Oil of the New Zealand School Shark (*Galeorhinus australis* MacLeay)

INVESTIGATIONS on the minor fatty acid constituents of the liver oil of the New Zealand school shark have resulted in the isolation of the saturated *n*-odd-numbered acids as well as the *iso*- and (+)*anteiso* acids of the C_{15} and C_{17} series[1,2]. These acids had not previously been found in fish oils, but had been earlier isolated from the depot[3] and milk fats[4] of ruminants. In addition, the occurrence of *n*-heptadecanoic acid and of (+)-14-methylhexadecanoic acid in tall oil has been established[5]. The occurrence of *n*-odd-numbered unsaturated acids in animal depot fats was first recorded in lamb caul fat, from which Δ^9-heptadecenoic acid was isolated[6] and the presence of pentadecenoic acid indicated: Δ^9-heptadecenoic acid has also been obtained from musk-ox fat[7] and from butterfat[8]. Following the feeding of *n*-odd-numbered saturated fatty acids, Appel, Böhm, Keil and Schiller[9] found that the corresponding Δ^9-mono-unsaturated acids were deposited in the depot and milk fats of goats and sheep. Apart from the above-mentioned instances, however, *n*-odd-numbered unsaturated acids have not been isolated from depot fats.

In shark liver oil, following extensive ester fractionation and low-temperature crystallization, fractions containing concentrates of *n*-mono-unsaturated acids of the C_{15}, C_{17} and C_{19} series have been prepared. These fractions have now made possible the isolation of Δ^9-heptadecenoic acid in pure form, and of Δ^{11}-nonadecenoic acid as a concentrate (73 per cent) with positional isomers mainly Δ^{10}- (13 per cent) and Δ^{12}- (14 per cent) nonadecenoic acids as impurities as judged from the yields of dibasic acids produced by oxidation using the method of Haverkamp Begemann *et al.*[10]. The resolution of these positional isomers is likely to prove difficult in contrast to the Δ^9-heptadecenoic acid, which was relatively easy to crystallize in pure form. From the weights of the concentrates and the results of gas-liquid chromatographic analysis it is estimated that pentadecenoic acid, Δ^9-heptadecenoic acid and Δ^{11}-nonadecenoic acid respectively form 0·018, 0·073 and 0·042 per cent of the shark liver oil fatty acids. These results serve to extend the similarities of ruminant fats and shark liver oils in regard to the occurrence of *n*-odd-numbered saturated and unsaturated fatty acids in addition to *iso*- and (+)-*anteiso*-acids of the C_{15} and C_{17} series earlier reported. Work on the isolation of the *n*-odd-numbered mono-unsaturated fatty acids is being continued.

Scorpamins: the Toxic Proteins of Scorpion Venoms

FOLLOWING preliminary work[1,2], extensive purification of the toxins secreted by two species of North-African scorpions (*Androctonus australis* and *Buthus occitanus*) was accomplished by aqueous extraction, acetone fractionation in the cold, chromatography on 'Amberlite *CG* 50' and filtration on dextran gel ('Sephadex *G* 25'). Table 1 summarizes the steps of purification from the glands.

Comparative experiments were performed, starting with the organ containing the venom glands (telson) or with the emitted venom obtained by a manual or an electrical method previously described[4]. The

See Table 1 for explanations of abbreviations.

* Column dimension, 4 cm. × 145 cm.

† One LD_{50} corresponds to 1·0 μgm. of pure toxin.

purification procedure is less tedious starting with the desiccated venom according to its higher toxin content (Table 2). The yield in pure toxin is about 30 per cent in these conditions.

The material obtained after the last step on 'Amberlite *CG* 50' was homogeneous with regard to chromatography (constant specific activity) (Fig. 1), electrophoresis and in the ultracentrifuge.

Two proteins, sharing almost equally the total toxic activity, have been separated from the venom of both species (Fig. 1). Their properties are very similar considering specific activity (the two toxins of *A. australis* and one of the two toxins of *B. occitanus* have specific activity of about 500), molar extinction coefficient and symptomatology of the intoxication in mice.

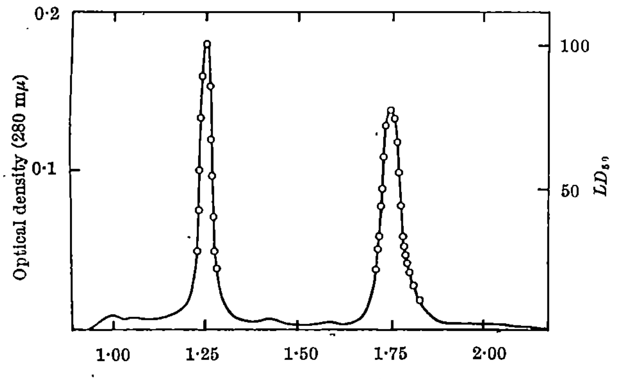

Fig. 1. Chromatographic homogeneity test of the pure toxins of *A. australis* on 'Amberlite *CG* 50' (4 cm. × 145 cm. column) equilibrated with ammonium acetate 0·2 *M*, *p*H = 6·80. Venom obtained by the manual method after filtration on 'Sephadex *G* 25'. The curve in full line corresponds to the optical density at 280 mμ. Open circles express the toxic activity in LD_{50} for the 20-gm. mouse, tested in several tubes of the separated peaks

Preliminary investigations indicate a molecular weight of 12,000 for the toxic proteins of *B. occitanus*, and a pH_i around 8·5 for the toxins of both species. The generic name of scorpamins has been given to the toxins of scorpions[2].

The venom collected by the manual technique is better for obtaining the pure toxins with a good yield (Table 2). The main characteristics of scorpamins are: (1) their pure neurotoxic effect; (2) their low molecular weight; (3) their high resistance to storage and denaturating agents. With regard to these properties, scorpamins constitute a remarkable material for the study of mechanism of action of neurotoxic proteins.

Full details of these experiments will be published elsewhere.

Reaction of Antimony Pentachloride with Pregnane-3α, 17α, 20α-Triol, Pregnane-3α, 17α, 20α-Triol-11-One and Other Adrenal Cortical Steroids

Antimony pentachloride has been used for detecting a number of steroids on paper chromatograms[1-4]. Pregnane-3α, 17α, 20α-triol (pregnanetriol) and pregnane-3α, 17α, 20α-triol-11-one (pregnanetriolone) can be detected on paper chromatograms by the method of Finkelstein and Cox[5] in which 70 per cent phosphoric acid induces a pink fluorescence in the former and a brilliant blue fluorescence in the latter when viewed with a long-wave (3660 Å.) ultra-violet lamp. However, the phosphoric acid gradually destroys the chromatogram paper, which necessitates delicate manipulation to avoid shredding.

We have found that antimony pentachloride can be used as a detecting agent for both pregnanetriol and pregnanetriolone.

Pregnanetriol (obtained from Mann Research Laboratories, Inc., New York, N.Y., and Sigma Chemical Co., St. Louis, Missouri); pregnanetriolone (obtained from Dr. W. Klyne, Steroid Reference Collection, Postgraduate Medical School, London, and Dr. M. Finkelstein, Hormone Research Laboratory, Hadassah Medical School, Jerusalem); pregnane-3α, 11β, 17α, 20α-tetrol (pregnanetetrol), and pregnane-3α, 17α, 20β-triol-11-one (pregnanetriol β-epimer) (obtained from Dr. D. Fukushima, Sloan-Kettering Institute, New York, N.Y.) were placed on Whatman No. 1 paper in 50-μgm. amounts and sprayed with 20 per cent antimony pentachloride in chloroform (20 gm. in 100 ml.). Immediately the pregnanetriol and pregnanetetrol turned yellow in colour. The pregnanetriol darkened and turned dark brown, while the pregnanetetrol changed to a bright blue colour. Pregnanetriolone in 50-μgm. amounts gave a yellow colour. With less than 50-μgm. amounts the pregnanetriolone and the pregnanetriolone β-epimer gave no visible reaction.

The paper was then heated for 5 min. at 78° C. The pregnanetriol became blue-grey in colour, and the pregnanetetrol became brown-grey. The pregnanetriolone became yellow in colour, while the pregnanetriolone β-epimer became faint yellow. Table 1 summarizes the results. Before heating only 50 μgm. of pregnanetriolone could be detected, while at least 5 μgm. of pregnanetriol gave a colour reaction. After heating, 5 μgm. of pregnanetriolone was faintly visible.

Table 1. REACTION OF ADRENAL CORTICAL STEROIDS WITH ANTIMONY PENTACHLORIDE

Compound	Colour before heating	Colour after heating
Pregnane-3α, 17α, 20α-triol	Yellow → dark brown	Blue-grey
Pregnane-3α, 11β, 17α, 20α-tetrol	Yellow → blue	Brown-grey
Pregnane-3α, 17α, 20α-triol-11-one	No colour	Yellow
Pregnane-3α, 17α, 20β-triol-11-one	No colour	Faint yellow
Hydrocortisone	No colour	Pale yellow
Cortisone	No colour	Very faint yellow
Corticosterone	No colour	Yellow
11-Deoxy-17 hydroxycorticosterone	No colour	Grey
11-Dehydrocorticosterone	No colour	Very faint yellow
11-Deoxycorticosterone	No colour	Blue

Other steroids including hydrocortisone, cortisone corticosterone, 11-deoxy-17 hydroxycorticosterone, and 11-dehydrocorticosterone gave no colour reaction with antimony pentachloride before heating. However, after heating for 5 min. at 84° C. corticosterone gave a yellow colour, 11-deoxycorticosterone a blue colour, 11-deoxy-17-hydroxycorticosterone a grey colour, and hydrocortisone a pale yellow. Cortisone and 11-dehydrocorticosterone gave very faint yellow colours which might not be detected if one did not know exactly where the compounds were located. These results are shown in Table 1.

These reactions with antimony pentachloride have been very useful in locating these various steroids on paper chromatograms because of the simplicity of the method.

Action Pattern of β-Amylase

CURRENT opinion with respect to the action pattern of β-amylase on amylose is divided into three divergent points of view: (1) single-chain pattern, in which β-amylase, having commenced attack on a given amylose molecule, completely hydrolyses this molecule to maltose before attacking another molecule; (2) multi-chain pattern, in which β-amylase removes a single maltose molecule from the non-reducing terminus of an amylose molecule, then completely separates from the substrate molecule and continues the attack on other amylose molecules in the same way; (3) multiple attack, in which β-amylase remains associated with a given amylose molecule long enough to remove, on the average, several molecules of maltose before attacking another amylose molecule. Substantial evidence exists which can be interpreted in favour of each of these points of view[1-6].

The principal evidence for the single-chain pattern is that at intermediate stages during action of β-amylase on amylose, the residual amylose remains essentially unchanged with respect to such properties as molecular weight, viscosity, and iodine colour[1-4]. With multi-chain or multiple attack it would be expected that the molecular weight of the remaining amylose would gradually decrease during β-amylase action. A critical feature of this interpretation, which has not been adequately considered, is the nature of the chain-length distribution of the original amylose as well as that of the amylose remaining at intermediate stages of hydrolysis. Specifically, if the molecular weight distribution of the original amylose is the 'most probable' distribution[7], any of the three

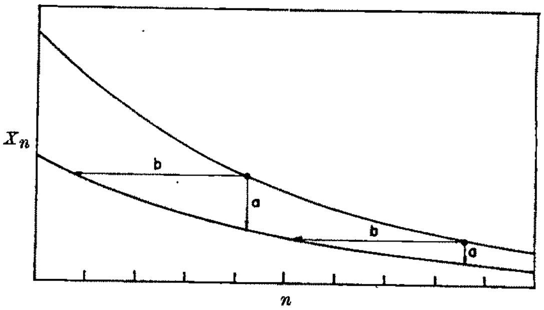

Fig. 1. Attack of 'most probable' amylose by (*a*) single-chain. (*b*) multi-chain action patterns. In (*a*) the number X_n of chains of a given length n is reduced by a given proportion. In (*b*) each chain is shortened by a given amount. The two action patterns are seen to give rise to identical distributions at intermediate stages of degradation. X_n and n are on an arbitrary scale

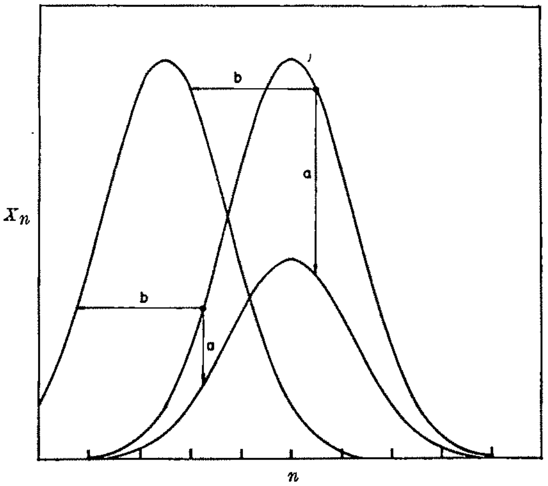

Fig. 2. Attack of 'normal distribution' amylose by (*a*) single-chain, (*b*) multi-chain action patterns. With (*a*) the distribution is unchanged but with (*b*) the average molecular weight is much reduced

suggested action patterns will lead to average molecular weights and size distributions of the residual amylose precisely the same as those of the original amylose. On the other hand, if the distribution of the original amylose is of the Gaussian or Kraemer-Lansing type, multiple attack or multi-chain action patterns would lead to products of substantially lower average molecular weight. These statements, illustrated qualitatively in Figs. 1 and 2, have been proved by exact mathematical analysis. For multiple attack the results are similar to those with the multi-chain pattern.

Most recent evidence is that native amylose corresponds to the 'most probable' distribution[8]. Moreover, while random degradation during preparation of amylose will reduce its average molecular weight, it is expected that the degraded material will still correspond to the 'most probable' distribution[7]. Hence, with native or unfractionated degraded amylose, one cannot distinguish between single-chain, multi-chain, and multiple-attack action patterns.

On the other hand, by synthesis or fractionation, it should be possible to produce high-molecular-weight amylose preparations with molecular size distributions significantly different from the 'most probable' distribution[9], and such materials are the only suitable substrates for definitive studies of the action pattern of β-amylase on high-molecular-weight amylose.

A Difference between the Modes of Action of Substrate and Hormonal Inducers of Rat Liver Tryptophan Pyrrolase

THE level of tryptophan pyrrolase can be greatly increased in rat liver by the intraperitoneal injection of tryptophan[1], cortisone[2] or hydrocortisone[3]. The administration of adrenocortical hormones is not associated with an increased level of tryptophan in the liver[3]. Moreover, cortisone is a non-specific inducer, in that it affects the levels of several liver enzyme systems[2]. Reserpine[4] has also been shown to increase the level of activity of tryptophan pyrrolase, and since it does not elicit this response in hypophysectomized rats, it has been suggested that its effect is mediated by the pituitary–adrenal system[5]. The present work indicates a qualitative difference in the mode of action of tryptophan on one hand and cortisone and reserpine on the other in the induction of tryptophan pyrrolase.

It has been shown previously[6,7] that rat liver tryptophan pyrrolase is located in the particle-free cell sap and that microsomes, owing to their iron-protoporphyrin content, can activate the enzyme of normal rat liver to a value approximately three times that of unsupplemented cell sap. It can be seen from Fig. 1 that the addition of liver microsomes, from either cortisone-treated or normal rats, causes similar relative increases in the tryptophan pyrrolase activity of liver cell sap preparations from both normal and cortisone-treated rats. Thus, following cortisone treatment, the rise in enzyme-level is not accompanied by a significant increase in the relative amount of available activator. Similar results were obtained when using reserpine as the inducing agent. Table 1 summarizes these results and contrasts them with those obtained following treatment with tryptophan. It can be seen that whereas the ratio of unstimulated to fully stimulated cell sap tryptophan pyrrolase activity has not been changed significantly by treatment with cortisone or reserpine, it has been greatly increased by tryptophan treatment. Although the maximal activity obtainable, presumably reflecting the amount of tryptophan pyrrolase apoprotein, was the same following administration of either tryptophan or cortisone, the effective enzyme activity (in

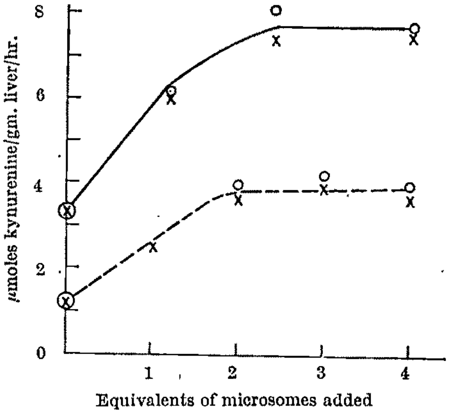

Fig. 1. Effect of microsomes on liver cell sap tryptophan pyrrolase activity of normal and cortisone-treated rats. Liver microsomes and particulate-free cell sap were obtained from normal rats and from rats killed 2 hr. after intraperitoneal administration of cortisone (10 mgm./kgm.). Normal cell sap (– – –) ; cortisone-cell sap (——) ; normal microsomes (×) ; cortisone-microsomes (○). The addition of one equivalent of microsomes restores the microsome–cell sap ratio to that of unfractionated liver homogenate

Table 1. INDUCTION OF TRYPTOPHAN PYRROLASE BY DIFFERENT AGENTS

Cortisone ('Cortisoneacetate', Merck) (0·01 gm./kgm.) and L-tryptophan (1 gm./kgm.) were injected intraperitoneally, and reserpine ('Serpasil', Ciba) (0·001 gm./kgm.) subcutaneously. The four equivalents of microsomes employed gave maximal stimulation

Substance injected	Hours post-injection	Tryptophan pyrrolase activity (μmoles kynurenine/gm. liver/hr.) Unsupplemented cell sap	Cell sap + four equivalent microsomes
—	—	1·6	5·9
Tryptophan	1	3·8	6·0
	2	8·4	8·8
	4	13·0	15·8
Cortisone	1	2·0	5·2
	2	2·8	8·0
	4	4·8	16·0
Reserpine	2	2·6	4·4
	4	3·6	7·8

the absence of added activator) was much greater following treatment with tryptophan.

Previous work with tryptophan[7] suggested that the activation of tryptophan pyrrolase provides the stimulus for induction (defined as increase in total obtainable activity). In the case of cortisone and reserpine, such an activation does not take place, indicating an alternative mechanism for the initiation of enzyme induction.

Biosynthesis of Citrulline in Plants

IN 1930 citrulline was discovered in water-melons[1]. Later it was shown to be an important participant in the Krebs and Henseleit ornithine cycle in animals and micro-organisms. In recent years several laboratories have worked on the ornithine cycle in plants. In this laboratory citrulline has been shown to play an important part in transporting and storing nitrogen in several families of higher plants[2–4]. Relatively high concentrations of citrulline in exuding sap and citrulline accumulated in artificially rooted leaves of alder trees show the root to have a determining influence in the biosynthesis of citrulline. However, excised branches of alder and hazel could also synthesize citrulline from ammonium nitrate under aseptic conditions. Though ornithine, the precursor of citrulline, is metabolized very quickly, we could not find significant amounts of it, but very high concentrations of the mono-N-acetyl-ornithine were found in all members of the family Fumariaceae, being characteristic of this family[5]. Ornithine reacting with carbamyl phosphate in the presence of carbamyltranspherase is converted into citrulline. My experiments have shown this reaction to occur under physiological conditions even without enzyme, though converting carbamyl phosphate much more slowly to cyanate, which reacts with the amino-groups[6,7]. It was also possible to establish the biosynthesis of citrulline from ornithine and carbamyl phosphate in higher plants[8–11].

To examine the possibility of activity of carbamyl phosphate in seaweeds, different green, brown, and red algae were ground in a mortar with *tris* buffer *p*H 8 at + 4° C. The extract, being usually weakly acid, was brought up to *p*H 8 with sodium bicarbonate, centrifuged (30 min. at 7,000 r.p.m. at 5° C.), and incubated at 30° C. The reaction was stopped by freezing at – 20° C., and the lyophilized reaction mixture re-solved with 70 per cent ethanol immediately before determination. After separation on paper chromatograms the amino-acids were determined colorimetrically with ninhydrin by comparison with standards[4].

The results given in Table 1 show that green and red seaweeds are able to synthesize citrulline from ornithine and carbamyl phosphate. 70–80 per cent of the ornithine was metabolized within the period of reaction. During this time some amino-acids increased also; primarily citrulline and glutamic as well as aspartic acid in small amounts, but not arginine and urea. After 30 min. incubation I found most of the initially produced ornithine was metabolized to citrulline; and there is scarcely a difference between incubation for 30 min. or 6 hr. Before incubation I found a relatively high concentration of citrulline in *Gracilaria*; whereas citrulline synthesis does not occur in *Taonia*. For the present we must leave it undecided whether this lack of citrulline synthesis is dependent on the developmental state of the plant, or whether it is specific only to *Taonia* or for all brown algae, having a special place in the biochemistry of seaweeds.

Table 1. BIOSYNTHESIS OF CITRULLINE IN SEAWEEDS

The complete system contained: 10 μmoles ornithine, 10 μmoles carbamyl phosphate (CP), 5 μmoles magnesium chloride, 1 ml. plant extract (= 1·5 gm. fresh weight of algae extracted and made up to 1 ml. with *tris* buffer *p*H 8)

	μMoles citrulline/1 ml. plant extract			
	Complete system	Complete system	Without CP	Without ornithine
Time of incubation (hr.)	0·5	6	6	6
Green algae				
Cladophora prolifera	6·85	8·60	0	0
Ulva lactuca	3·43	4·00	0·80	0
Red algae				
Neomonospora furcellata	6·29	6·85	1·60	0·69
Gracilaria conferoides	12·00	14·85	8·60	6·58

A New Preparation of Gastrin: Preliminary Characterization

THIS Laboratory is examining the chemistry of 'gastrin', about which little has been reported. We have recently prepared a gastrin-like secretory stimulant from porcine antral mucosa by a new and somewhat novel method. This is a preliminary report on its chemical properties, and similar data on 'gastrin' as prepared by a more conventional procedure. The quotation marks signify only that it is not known whether gastrin is a single compound, or a group of similar structures with a common unique moiety, or a group of biologically, more or less, specific substances. The facts that gastrin has been reported as dialysable[1], non-dialysable[2], with an isoelectric point near *p*H 5·0 [3], or *p*H 8·0 [4], to name only a few of its properties, leave the question very much open. Recently, Gregory *et al.*[5] described a gastrin-like substance isolated from a pancreatic tumour.

Different from any method we have found in the literature of this substance, we have extracted gastrin from hog antrum with aqueous alkali, *p*H 11–12, at 40° C. Subsequent steps included isoelectric precipitations at *p*H 5·0, and precipitations in sodium chloride solution. At no time was the preparation more acid than *p*H 4·0, or warmer than 40° C. Dialysis of the crude material against running water and several changes of distilled water followed by lyophilization or isoelectric precipitation gave yields of 0·5–2·0 gm. per 20 antral mucosæ.

At this stage we have had consistently good stimulation. Solutions of 75–100 mgm. (as little as 50 mgm. has produced good response) in 50 ml. of sterile saline were injected during $\sim$30 min., using a motor-driven syringe. A sharp rise in secretory flow and of $[H^+]$ resulted, followed by a decline after the injection. For the half-hour of greatest activity, eleven experiments gave us an average rate of secretion of 12·4 ml./hr., and a rate of hydrogen ion production equivalent to 18·0 ml. of 0·01 *N* hydrochloric acid/hr. 80 per cent, or more, of these amounts represented increase over the base line. Our best eight experiments with material prepared by a modification of the Uvnäs method[3] gave comparable figures of 5 ml. (volume) and 10·6 ml. (0·01 *N* hydrochloric acid equivalent.

In our previous work on dialysed gastrin, as prepared by the Uvnäs method, we had often noted vomiting, or an inactive preparation, or acquired tolerance. In the dialysed material from the new method we have not observed such symptoms, and we have had no inactive preparations. Of considerable additional interest are the excellent results obtained with subcutaneous injections. A good flow persisted for 2½–3 hr. after the injection, contrasting with the rapid decline after histamine injection. One such active sample had been kept dry and in the dark at −20° C. for 8 months before the assay.

In the material prepared by acid extraction and trichloracetic acid precipitation[3] we had found a small but consistent content of phosphorus (average 0·05 per cent). We have found 10–15 times as much phosphorus in the new preparation (dialysed), that is, 0·5–0·8 per cent. Treatment with 0·25 *N* alkali at 27° C., isoelectric precipitation and re-dialysis did not lower the phosphorus content appreciably, making the presence of a typical phosphoprotein unlikely[6].

In the ash of the dialysed gastrin, as the only unique constituent in measurable quantity, we have consistently found tin. On standing in dilute stannous chloride and prolonged re-dialysis, the gastrin retained considerable metal ion (ash $\sim$1 per cent, of which $\sim$20 per cent was tin).

We have subjected the dialysed gastrin to diethylaminoethylcellulose ion-exchange treatment, Tiselius electrophoresis (one main component, through the kindness of Dr. P. D. Goldsworthy), and curtain electrophoresis with veronal buffer (*p*H 8·6, ionic strength 0·02) on Whatman 3-*MM* paper at 300–500 volts. The most interesting results have come from the last method. Electrophoresis of a 1 gm. sample of dialysed material led to recovery of 65 per cent (redialysed and lyophilized material). One main protein fraction was observed ($\sim$40 per cent) which migrated (minus to plus) a moderate distance, and gave strong colour with tetrabromophenolphthalein ethyl ester (potassium salt)[7]. Displaced further toward the positive pole, there was a smaller fraction (average 2–3 per cent after dialysis), which gave no protein colour test, and another protein-like material ($\sim$1 per cent). The phosphorus content of the main protein fraction was low (0·05 per cent or less); that of the non-protein fraction was high (4–7 per cent). The main fraction had an ultra-violet spectrum typical for proteins. The ultra-violet spectrum of the non-protein fraction had a sharp intense peak at 260 mμ. Much of the remaining phosphorus, which had not been accounted for, appeared to be on the curtain in the path of the main protein fraction. The latter appears to be bound to the high-phosphorus fraction somewhat tenaciously.

The protein after electrophoresis had considerably less secretory stimulant activity than the material before electrophoresis and appeared to be less stable. The dialysed gastrin and the main protein fraction on electrophoresis have each given a 10 per cent yield, or more, of crystalline material, as long fibrous needles, by an ammonium sulphate procedure. Full details of the extraction procedure, the chemical properties and our experience in tracing the activity will be presented shortly.

PHYSIOLOGY

Crystallization of Purines in the Vacuole of *Candida utilis*

We have reported previously that *Candida utilis* removes seven purines (adenine, guanine, hypoxanthine, xanthine, uric acid, 2,6-diaminopurine and *iso*guanine) from the medium by an active transport process when these compounds are used as sources of nitrogen for the yeast[1,2]. These compounds and their metabolic products are held within the cell in high concentrations that appear to exceed the solubilities of the compounds in the volume of water available. For example, 5 gm. (wet weight) of yeast that had taken up 450 mgm. of uric acid was dried to constant weight, samples of the dried yeast were heated repeatedly in buffer at 100° C. to extract the uric acid, and the extracts were analysed with purified uricase by the method of Kalckar[3]. It was found that the dried yeast contained 16 per cent uric acid by weight and that 35 per cent of the uric acid administered was recovered in the extracts. It is presumed that the remaining 65 per cent of the uric acid had been metabolized via the yeast uricase. The wet yeast contained 82 per cent water, so that the concentration of uric acid would be about 35 mgm./ml. of water in the wet yeast. The solubility of uric acid is given as 2·53 mgm./100 ml. at 20° C. (ref. 4) and therefore the presence of crystalline uric acid in the yeast cell would be expected with the high concentrations that were observed.

Microscopic examination of yeast cells that had accumulated purines revealed the presence of crystals in the vacuole. These were most evident in the case of *iso*guanine, which crystallized within the cell in needles that usually lay along the long axis of the cell and appeared to extend from wall to wall. To confirm the presence of purine crystals, yeast containing the various purines was treated with dilute silver nitrate to form the silver purines, washed, and treated with dilute sodium sulphide. The crystals became more striking because of blackening due to the formation of silver sulphide on the crystal surfaces; this was not observed with control yeast. Finally, when examined in the crossed field of a polarizing microscope, the crystals were seen as dots or lines of light that exhibited a twinkling effect due to Brownian movement in the case of smaller crystals. Cells that had not taken up purines remained dark in the crossed field.

It was found previously that the accumulated purines with the exception of *iso*guanine were slowly metabolized by the yeast[1,2]. Since it was considered possible that the presence of the crystals within the cell might disrupt the internal structure and interfere with normal growth, cells that contained *iso*guanine crystals or amounts of crystalline uric acid that occupied much of the vacuole were placed on nutrient agar on microscope slides and observed during the course of a day. Normal buds formed and grew from the cells containing either crystalline *iso*guanine or uric acid. Thus, it appears that growth and metabolic processes occur when the crystals are present, and it is evident that the uric acid crystals must slowly re-dissolve and be metabolized, because uric acid gradually disappears from the cells[1]. It is of interest to note that the accumulation of S-adenosylmethionine in the vacuole of *C. utilis* occurs without the appearance of crystals[5].

The crystallization of purines in *C. utilis* provides a useful system for the study of crystallization and crystal growth and dissolution processes within the living cell. The effect of purine crystallization on the active transport of the purines and on the induced formation of enzymes of purine metabolism in yeast is being studied. This investigation was supported by Research Grant *CY*2510 from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service.

Plasma Clot Dissolution by Urea Derivatives

A method for forming standard human plasma clots has been described in a previous communication[1]. This method allows an accurate measurement of the clot-dissolving activities of various compounds applied in solution to a standardized invariable surface. In this previous work it was found that when a plasminogen activator, such as urokinase, was applied to the preformed clot, it produced a progressive fibrinolysis. Afterwards it was observed that the presence of 'Tween 20' in the activator solution enhanced the activator-induced fibrinolysis. The question then arose as to whether or not denaturation of fibrin by any compound would enhance the fibrinolytic process. The first group of compounds studied, and that reported in this communication, was urea and urea derivatives. Urea, itself, is a well-known denaturing agent. It enhances proteolysis in lesser concentrations[2] and dissolves fibrin in greater concentrations[3].

All compounds studied with the standard clot were dissolved in human defibrinated plasma at various concentrations. These plasma solutions were then applied to the preformed standard clots (obtained by recalcifying of plasma) either in the presence of various concentrations of urokinase or in the absence of urokinase. The progress of the clot lysis at 37° C. was noted at intervals and expressed as percentage of clot lysed.

A number of urea derivatives were found which enhanced the urokinase-induced fibrinolysis of the preformed standard clots. The degree of enhancement of the urokinase-induced fibrinolysis was not the same for each compound. Among the compounds examined were ethyl urethan, methyl urethan, allylthiourea, urethan and urea. They are listed in order of activity with ethyl urethan showing the greatest enhancement and urea showing the least. The presence of ethyl urethan, methyl urethan and allylthiourea, at concentrations as low as 2 per cent, in solution with an ineffective amount of urokinase, still promoted fibrinolysis.

Controls for experiments using concentrations greater than 2 per cent revealed that some of the derivatives were dissolving the preformed plasma clot in the absence of urokinase. The effective concentrations were considerably lower than the

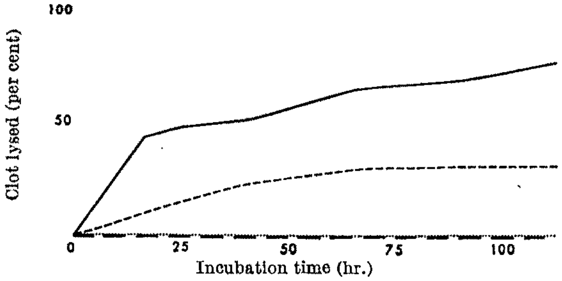

Fig. 1. Rate of dissolution of human plasma standard clots by urea and urea derivatives. ——, 0·4 *M* ethyl urethan; – – –, 0·4 *M* methyl urethan; . . . ., 0·4 *M* urethan; — —, 0·4 *M* urea

urea concentration required to dissolve fibrin clots. Fig. 1 shows a typical example of the dissolution of preformed plasma clots by urea derivatives in the absence of urokinase.

In the experiment represented in Fig. 1, urea and urethan were ineffective. It showed that the introduction of a methyl group into the urethan molecule, however, produces a clot-dissolving substance. Still greater clot-dissolving activity is obtained with the introduction of an ethyl group.

Further work with ethyl urethan revealed that plasma could be clotted after the addition of ethyl urethan in concentrations of 3 per cent or less. As with the preformed clots, it was noted that the fibrinolysis-inducing activity of urokinase is considerably enhanced under these conditions by the presence of ethyl urethan. An example of this is shown in Table 1, where ineffective concentrations of both urokinase and ethyl urethan are combined to produce lysis in a relatively short time.

Table 1. Enhancement of Urokinase Activity by Ethyl Urethan in Human Citrated Plasma

(All clots were formed with thrombin)

Plasma plus urokinase, 15 μgm./ml.	Plasma plus ethyl urethan, 0·5 per cent	Plasma plus urokinase, 15 μgm./ml., and ethyl urethan, 0·5 per cent
No lysis in 24 hr.	No lysis in 24 hr.	Lysis in 90 min.

When 2 or 3 per cent of ethyl urethan was incorporated into plasma clots, in the absence of urokinase, it dissolved the clot within a period of 16–30 hr. This 'chemical' lysis occurred regardless of the clotting technique (spontaneous, recalcification, or thrombin). Representative examples of dissolution of clots spontaneously formed in the presence of ethyl urethan are shown in Table 2. The human plasma was obtained by the silicone technique and afterwards permitted to clot in glass tubes. A firm clot was produced in each case.

Table 2. Dissolution of Human Plasma Clots formed spontaneously in the Presence of 2 per cent Ethyl Urethan

	Clotting time (min.)	Clot dissolution time (hr.)
Plasma *A*	15	23
Plasma *B*	19	22
Plasma *C*	10	30

As a working hypothesis and in analogy with the well-known protein-dissolving properties of higher urea concentrations, it is thought that ethyl urethan and other urea derivatives weaken the fibrin network by denaturation (breaking of hydrogen bonds). Denaturation is known to facilitate enzymatic hydrolysis. It has also been suggested that denaturation is a pre-requisite of any enzymatic degradation of proteins[4]. This would explain the marked enhancement of urokinase-induced fibrinolysis by these urea derivatives. This concept might also hold true for clots formed in the presence of ethyl urethan, but in the absence of urokinase which undergo subsequent dissolution. In this case the fibrin denaturation could have been carried to a point which permitted the endogenous 'masked' fibrinolytic activity of plasma[5] to dissolve the fibrin. We also have suggestive evidence that the urea derivatives described actually activate plasma plasminogen in the presence of the plasma factor (pro-activator ?)[6].

Urea at 30 per cent dissolves fibrogen clotted by thrombin, but does not dissolve clots formed in the presence of a stabilizing serum factor and calcium[7]. Urea was ineffective at the concentrations used in this study of urea derivatives. The urea derivatives found to dissolve plasma clots did so regardless of the method used for clotting and at concentrations of 2 or 3 per cent. This indicates that the mode of action of these compounds is quite different from that of urea.

There were relationships between the chemical structure of the derivatives and their clot-dissolving power. This relationship could be a useful starting point in the search for more powerful 'chemical' clot-dissolving agents. Further work is in progress in our laboratories.

Clotting-Time of Cold-exposed and Hibernating Hamsters

Prolonged blood-clotting in hibernating hamsters has been reported by Svihla *et al.*[1]. In another experiment with ground squirrels[2], it was concluded that the prothrombin-level decreased during hibernation, but the use of the one-stage prothrombin test for calculating prothrombin concentrations is questionable[3]. Suomalainen and Lehto[4] found that both naturally and artificially dormant hedgehogs had an increased clotting-time and increased heparinocyte counts of the small intestine and bronchioles.

The Syrian hamster (*Mesocricetus a. auratus*) requires several weeks of exposure to cold before entering hibernation. As a result, it has been possible to ascertain whether an increased clotting-time occurs gradually during the weeks of acclimation or is a phenomenon immediately preceding hibernation.

The hamsters were kept in a cold room at 5 ± 1° C. for varying periods of time. Each group contained ten animals, except for the hibernating group in which there were three animals. Each hamster had a separate cage with 'Purina' laboratory chow and water *ad libitum*. The first group lived in the cold

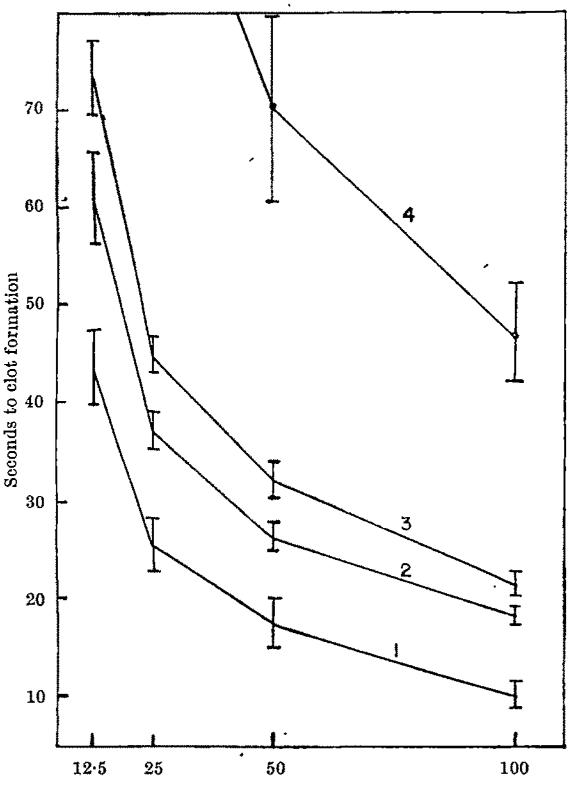

Fig. 1. Clotting-time with Russell's viper venom of various dilutions of plasma from hamsters exposed to cold (5 ± 1° C.) for (1) no weeks, (2) two weeks, (3) eight weeks, and (4) in hibernation

for 2 weeks, the second group for 8 weeks, and the hibernating animals had been in the cold for 12 or more weeks. The control animals were taken from the stock room at 22 ± 1° C. The animals were lightly anæsthetized with nembutal and the blood taken by cardiac puncture into a siliconed needle and syringe. The clotting times of 100, 50, 25 and 12·5 per cent plasma were determined in siliconed glassware at 37° C., using Russell's viper venom for the one-stage prothrombin time test.

In Fig. 1 the means of each group at the various dilutions of plasma are plotted with the vertical lines representing the standard errors. The Russell's viper venom time increased for each dilution as the cold exposure time of the animals increased. The increases in clotting-time from group to group for the various dilutions are relatively similar except for the hibernators. By 8 weeks of cold exposure the clotting-times are approximately between those of the control group and the hibernating group. This indicates that there has been a steady increase or decrease in some component of the plasma which affects the efficiency of Russell's viper venom. According to Fullerton and Anastasopoulos[5], Russell's viper venom is relatively insensitive to alterations in plasma prothrombin. De Beer[6] has shown that viper venom reveals both the intensity and duration of the anticoagulant activity of heparin. Therefore, the increased clotting-time of Fig. 1 cannot be explained as a reduction in prothrombin only and may reveal an increase in heparin.

Table 1. CLOTTING-TIME OF 100 AND 25 PER CENT PLASMA WITH RUSSELL'S VIPER VENOM AND THROMBOPLASTIN AND THE HEPARIN CONCENTRATION OF THE PLASMA OF HAMSTERS EXPOSED TO COLD (5 ± 1° C.)

Weeks in the cold 5 ± 1° C.	No. of animals	100 per cent plasma		25 per cent plasma and thromboplastin	
		Venom clotting-time (sec.)	Thrombo-plastin clotting-time (sec.)	Normal clotting-time (sec.)	Plasma heparin (γ/ml.)
0	8	14·1 ± 1·8	14·5 ± 1·4	23·6 ± 4·0	7·4 ± 1·4
8	7	25·1 ± 2·7	18·9 ± 3·2	22·4 ± 2·5	14·0 ± 1·6
12 (Hibernating)	3	47·3 ± 5·5	30·0 ± 4·5		

The heparin content of the blood from control hamsters and hamsters exposed to cold (5 ± 1° C.) for 8 weeks was determined by a protamine titration technique[7]. The test was modified by adding 5γ rather than 10γ of exogenous heparin (Connaught Laboratories) to the plasma. The results are summarized in Table 1. The concentration of heparin, as measured by this test, was increased twofold in the blood of hamsters exposed to cold for eight weeks. With 100 per cent plasma there was no significant difference in the clotting-time between the venom and brain thromboplastin. After 8 weeks in the cold, the clotting-time was more prolonged with venom but not with thromboplastin. The clotting-time of 100 per cent plasma as determined previously on hibernating hamsters was very significantly increased with both venom and thromboplastin. With 25 per cent plasma and thromboplastin, there was no increase in the clotting-time at 8 weeks, although as seen from Fig. 1 there was a significant increase at this dilution with venom. Some plasma component to which Russell's viper venom, but not thromboplastin, is very sensitive significantly altered in 8 weeks of cold exposure.

Clotting-time with Russell's viper venom is affected by the concentration of plasma lipid, and plasma deprived of lipid will not clot with this venom[5]. In view of this, the present results indicate that the concentration of plasma lipid altered during the prolonged cold exposure. This lengthened the clotting-time with the venom and had only a slight effect on the activity of brain thromboplastin. The accompanying increase in plasma heparin is probably related to the change in plasma lipid since heparin is believed to be involved in fat transport[8]. The highly significant increase in clotting-time during hibernation probably arises from a combination of reduced prothrombin synthesis, resulting from a general lowering of body metabolism, and a high concentration of some heparinoid substance in the plasma.

Bile Pigment Excretion in Amphibia

In man and in other mammals, bilirubin is excreted in conjugated form, mainly as the glucuronide. Since in mammalian fœtal liver the enzymatic mechanism for glucuronide formation is poorly developed, reaching its full capacity only after birth, transient hyperbilirubinæmia is frequently observed during the neonatal period[1]. In the amphibian genus, *Rana*, hepatic glucuronide formation is absent in the larva, but present in the adult[2]. The larval forms undergo extra-uterine development and hence are readily accessible. These Amphibia would represent an excellent experimental model for studying various aspects of neonatal hyperbilirubinæmia, if it could be established that they, like mammals, excrete bilirubin as glucuronide. Therefore, we have examined amphibian bile pigment excretion to determine, first, whether in the adult *Rana* bilirubin is excreted as a glucuronide; secondly, whether metamorphosis is associated with qualitative or quantitative changes in pigment excretion; and thirdly, whether the excreted pigment is biliverdin, as has been postulated previously[3], bilirubin, or another pigment.

Larval forms of *Rana catesbiana* and adult forms of *Rana pipiens*, *Xenopus laevis*, and *Necturus maculosus* were examined. The last two remain aquatic throughout adult-hood; in addition, *N. maculosus* fails to metamorphose while achieving sexual maturity. As expected[2], hepatic glucuronyl transferase activity was demonstrable only in adult *R. pipiens* but was lacking in the liver of the larvæ, and the two adult aquatic Amphibia (Table 1).

Table 1. ENZYMATIC SYNTHESIS OF *o*-AMINOPHENYL GLUCURONIDE BY LIVER HOMOGENATE FROM AMPHIBIAN SPECIES

Species	Sex	No. of assays and incubation temperature (°C.)	*o*-Aminophenyl glucuronide formed: Average	Range
R. catesbiana, larvæ	M, F (pooled)	2; 21	not demonstrable	
R. pipiens, adults	M	6; 37	0·363	0·279–0·412
		6; 21	0·290	0·260–0·344
X. laevis, adults	M	4; 37	not demonstrable	
		2; 21	not demonstrable	
N. maculosus, adults	M	2; 37	not demonstrable	
		2; 21	not demonstrable	

Liver was homogenized with 5 parts of 0·154 *M* potassium chloride. 1 ml. of homogenate was incubated for 30 min. in air with 30 μM magnesium chloride, 1·0 μM uridine diphosphate glucuronic acid, 0·125 μM *o*-aminophenol and 0·1 ml. 0·5 *M* phosphate buffer *p*H 8·0; final incubation mixture was 1·5 ml. (ref. 6). Results are expressed in μmoles per gm. of liver.

The gall-bladder bile of adult *R. pipiens* invariably contained bilirubin (Table 2) and frequently biliverdin[4], but on paper chromatographic analysis[5] bilirubin glucuronide could not be demonstrated. The bile of *X. laevis* and *N. maculosus* usually exhibited high concentrations of bilirubin (Table 2) and occasionally some biliverdin. The bile of *R. catesbiana* larvæ, though yellow or green in colour, contained only trace amounts of bilirubin and biliverdin and gave a negative Gmelin reaction. Similarly, in adult *R. pipiens*, *X. laevis* and *N. maculosus*, but not in larvæ of *R. catesbiana*, urobilinogen was present in the intestinal tract. The serum of all adult species examined was colourless or only faintly yellow. Larval serum, on the other hand, was intensely yellow with peak absorption at 4600 Å., suggesting the possible presence of bilirubin. The diazo reaction, however, gave only insignificant spectrophotometric readings, and it was not possible to establish that the yellow pigment was a bilirubinoid compound.

Table 2. BILE PIGMENTS IN AMPHIBIAN BILE AND INTESTINAL CONTENT

Species	Gall bladder: Weight (mgm.)	Gall bladder: Bilirubin content* μgm. per gall bladder	Intestinal urobilinogen†
R. catesbiana, larvæ	19·4–33·5	0–0·2	absent
R. pipiens, adults	17·6–42·6	9·3–47·0	present
X. laevis, adults	72·6–75·8	1·6–43·0	present
N. maculosus, adults	198·0–230·0	53·0–54·0	present

* Bilirubin was determined by the diazo reaction (ref. 7).

† Urobilinogen was identified spectroscopically with *p*-dimethylaminobenzaldehyde (ref. 4).

These observations indicate that, in adult Amphibia, biliary excretion of bile pigment is independent of the presence of a functioning mechanism for glucuronide formation. Moreover, in adult *R. pipiens* no evidence was obtained for excretion of bilirubin as a glucuronide, even though glucuronyl transferase is present in the liver. In larvæ, the finding of yellow serum, the virtual absence of bilirubin and biliverdin in the bile, and the absence of urobilinogen from the intestinal tract suggest a mode of bile pigment excretion different from that in adult animals. Finally, in contrast to earlier reports[3], the bile of all adult animals contained bilirubin while biliverdin could not be demonstrated in all instances.

Fractionation of the Motor Unit during Repetitive Response to Prostigmine

Recent work has demonstrated fractionation of the action potential of the single motor unit of the rat gastrocnemius into anatomically unidentified sub-units[1]. The temporal sequence of firing of these sub-units can be altered by intravenous administration of curare or decamethonium. These drugs, by reducing the end-plate potential, increase the latency of appearance of the propagated spike of some, but not all, of the sub-units which comprise the action potential of the single motor unit. When the time of rise for the end-plate potential of the sub-unit is sufficiently prolonged, the propagated spike of the sub-unit disappears[2], and the total unit potential is reduced. In order to evaluate the effect of prostigmine on the single motor unit, the work reported here was undertaken.

Under intraperitoneal sodium pentobarbital anæsthesia, laminectomy was performed in 18 male albino rats, weighing 250–400 gm. With binocular magnification of × 25, a ventral root innervating the gastroc-

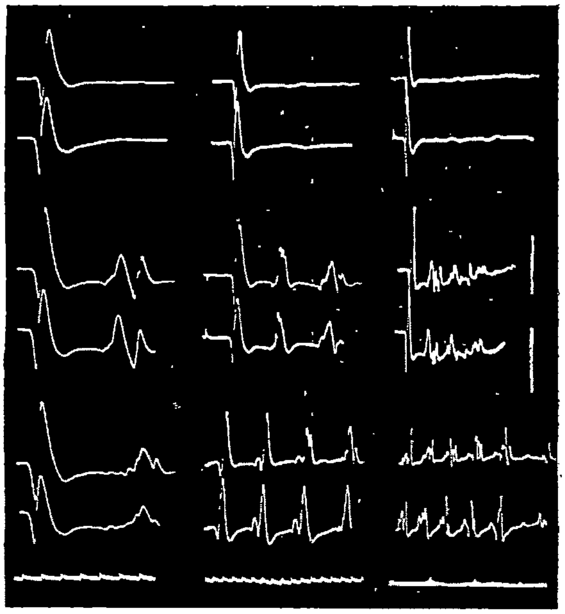

Fig. 1. Response of motor unit to prostigmine. Upper pair of traces, control responses of single motor unit of gastrocnemius to single stimulus delivered to ventral root filament. Middle and lower pairs of traces, random frames following intravenous administration of 0·02 mgm. prostigmine. Rhythmic repetitive responses to a single stimulus delivered to a ventral root filament occur at 4 msec. intervals. The second and subsequent responses reveal decreased amplitude and increased duration secondary to the asynchrony of firing of the 'sub-unit'. Time: cols. 1 and 2, 1 msec.; col. 3, 10 msec. Calibration, 0·1 mV. upper channel; 0·2 mV. lower channel

nemius was separated from the spinal cord and teased into fine filaments, one of which was stimulated with a rectangular pulse of 0·02–0·05 msec. delivered from a Grass 3*C* stimulator. A single motor unit on the surface of the gastrocnemius was identified with two pairs of bipolar recording electrodes made of enamel-insulated copper wire of 140μ diameter, was amplified with a low-level a.c. pre-amplifier and displayed on a dual-beam oscilloscope. Spinal cord, nerve roots and gastrocnemius were maintained at body temperature in small mineral oil pools. The presence of a single unit was determined by a sharp threshold of stimulus strength, below which no response appeared, and above which response form remained unaltered. A series of control responses was photographed at a stimulus strength of at least three times threshold, and intravenous prostigmine methylsulphate was administered in doses of 0·012–0·0375 mgm. The response of the motor unit was followed photographically every 3–6 sec.

Within 38–150 sec. following administration of the drug, multiple responses to the single stimulating shock appeared (Fig. 1). The second and subsequent responses showed fractionation of the action potential of the single unit into component sub-unit potentials, similar to the fractionation that had been demonstrated in the single response to a stimulus following administration of a blocking agent. The duration of the initial response remained at control value following administration of prostigmine; the amplitude of the initial response either remained at control value or increased to a maximum of 27 per cent (Fig. 1, channel *A*) until late in the experiment when a fall of amplitude was ascribed to deterioration of the preparation.

In three animals doses of prostigmine ranging from 0·25 to 1·0 mgm. were used. Repetitive responses failed to appear following this larger dose, and no change in duration or form of the motor unit response occurred. Fasciculation of the gastrocnemius was always visible at the time of onset of repetitive responses, but was not apparent following the larger dose of prostigmine.

Repetitive response of eserinized muscle was described by Brown[3], and has been thought to result from prolonged local potentials at the end-plate[4]. Riker *et al.*[5], and more recently Werner[6], have suggested the repetitive response of muscle to a single impulse in nerve results from the physiological independence of the nerve terminals. Following administration of quaternary ammonium derivatives or physostigmine, single or repetitive post-synaptic orthodromic responses were associated with repetitive antidromic axonal responses. These authors suggest initiation of the repetitive activity at the nerve terminal. The present findings, which demonstrate fractionation of the repetitive responses, would indicate either that the generation of repetitive impulses in the nerve terminals following administration of prostigmine is asynchronous, or that the effect of the drug on the subneural apparatus of a single motor unit permits asynchronous firing of the sub-units. The nature of the sub-unit is still unknown.

Effect of Artificial Fever in Increasing Susceptibility to Bacterial Endotoxin

THERE is remarkably little information concerning the effect of fever on mechanisms of resistance to infection[1]. Indications of a potentiating effect of high ambient temperatures on mortality in mice challenged with endotoxin or with Gram-negative bacilli have been recorded[2–4]. Recently, Bannister[5] has observed that high ambient temperatures potentiate the febrile response to pyrogenic doses of endotoxin in human volunteers. Burack has observed that the Shwartzman response in the skin of rabbits is also conditioned by the environmental temperature[6]. Work on the effect of environmental temperature on the lethality of endotoxin was therefore undertaken.

Webster–Swiss strain mice, weighing 9–12 gm., were given graded doses of *S. typhosa* endotoxin intraperitoneally. The endotoxin, extracted as previously described[7], was dissolved in sterile saline. No striking sex difference in susceptibility to endotoxin was observed. However, in each experiment mice of a single sex were used. When mice were maintained in an air-conditioned room at 22° C., the LD_{50} of the endotoxin varied between 400 and 800 μgm. When mice were placed in a well-ventilated incubator at 37° C. for 24 hr., and then given endotoxin and placed back at 22° C., the LD_{50} was not significantly altered (Table 1). Mice that were maintained at 22° C., given endotoxin and placed immediately at 37° C., had an LD_{50} of but 21 μgm. (range 11–23 μgm. in repeated experiments). Mice pre-incubated at 37° for 24 hr., given endotoxin and then returned to the 37° C. environment had an LD_{50} of less than 1 μgm. Deaths were not observed in control animals injected with saline and maintained at either temperature. Thus, the effect of raising the ambient temperature was to increase susceptibility to the lethal action of endotoxin.

Table 1. EFFECT OF ENVIRONMENTAL TEMPERATURE ON LETHAL ACTION OF BACTERIAL ENDOTOXIN IN MICE*

Environmental temperature		
Pre-injection	Post-injection	LD_{50} (μgm.)
22° C.	22° C.	500
37	22	732
22	37	21
37	37	$<0·96$

* Female mice weighing 9–12 gm.

The mode of death differed in accordance with the environmental temperature. At 22° C. there was a lag period of several hours, with no apparent evidence of distress, followed by increasing tremulousness and gradual suppression of activity, with death occurring 12–18 hr. after administration of endotoxin. At 37° C., on the other hand, mice appeared quite well for 2–4 hr., then suddenly developed convulsive seizures with collapse and death occurring shortly thereafter.

In order to determine the effect of environmental temperature on the body temperatures of the animals, rectal thermistor probes in fine plastic catheters were inserted, and the mice were restrained from interfering with the probes by immobilization in loose envelopes constructed of ¼-in. open-mesh plastic screening. These envelopes permitted a moderate amount of muscular activity and free exposure to the ambient air. Temperatures were recorded every 15 min. using an electronic recorder, and observations were made for three hours.

Hypothermia was invariably observed in mice kept at 22° C. and given endotoxin, as has been observed by others[8]. Uninjected mice varied in body temperature but consistently increased their body temperatures when placed in an incubator at 37° C. The increased body temperature was sustained during the three hours of incubation, reaching a maximum at about 1 hr. and remaining relatively constant thereafter. However, when mice were given a large dose of endotoxin (1 mgm. per mouse) and placed at 37°, the febrile response was invariably greater than that observed in control animals given saline and kept at the same temperature. Similarly, mice that were given endotoxin after having been kept in the incubator for two hours underwent a still further rise in temperature during the next few hours, whereas animals given saline alone maintained relatively constant temperatures with continued incubation. About 2/3 of the animals receiving 1 gm. of endotoxin died during the 3-hr. period of observation at 37° C., and deaths coincided with rapid elevation of body temperatures to values greater than 41·5° C.

These experiments indicate: (*a*) that elevation of environmental temperature increases susceptibility to the lethal action of endotoxin; (*b*) that careful control of body temperature in experiments employing lethal doses of endotoxin is essential; (*c*) that mice may develop fever when given endotoxin if their body temperatures have initially been elevated; (*d*) that the increased susceptibility to endotoxin and the sudden death seem to be related to the increased body temperature of the host animal.

HÆMATOLOGY

A New Hæmoglobin Variant (the 'Honolulu Type') in a Chinese

RECENTLY several hæmoglobin variants have been described with electrophoretic mobilities between those of hæmoglobins *G* and *S* in paper electrophoresis, veronal buffer, *p*H 8·6, namely, types *L* (ref. 1), *P* (refs. 2 and 3), and Stanleyville I (refs. 4 and 5). One case of hæmoglobin *G* was found in a Chinese[6]. The present report deals with a new hæmoglobin variant in a Chinese, similar to *L*, *P* and Stanleyville I in paper electrophoresis, but distinguished from them by chromatography or free electrophoresis.

The variant was found in a forty-three-year-old unmarried woman, J. C., a resident of Honolulu, whose condition was termed 'anæmia' by a local physician about three years ago. The initial red blood cell count was 4·5 million per mm.³ and the hæmoglobin 10·4 gm. per cent; after iron therapy the red cell count increased to 6·0 million and the hæmoglobin to 12 gm. per cent. About seven months ago, J. C. consulted another physician for the complaints of

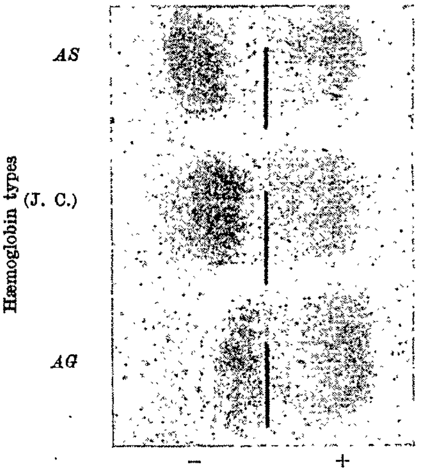

Fig. 1. Paper electrophoresis pattern of J. C.'s hæmoglobin sample compared with *AS* and *AG*, veronal buffer, *p*H 8·6, μ 0·05

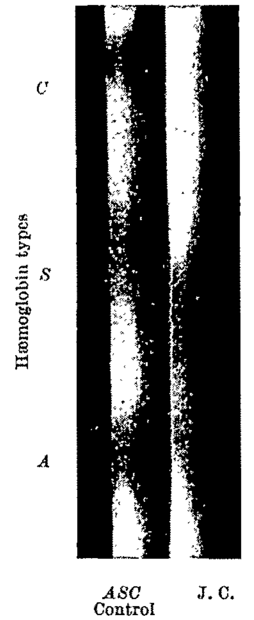

Fig. 2. Chromatography of hæmoglobin of J. C., 'Amberlite *IRC*-50', citrate buffer, *p*H 6·0, compared with *ASC* control

fatigue, pruritus ani, and anxiety ; at that time sternal bone marrow puncture revealed active erythropoiesis, with normally cellular marrow, but deficient in iron stores. Two months later (after iron therapy) she was examined by one of us (R. T. S. J.), who obtained the following laboratory data : red blood cells, 4·8 million, hæmoglobin 12·6 gm. per cent, reticulocytes 1 per cent (Dameshek method), with slight anisocytosis, poikilocytosis, occasional microcytic hypochronic cells and occasional target cells. The serum bilirubin value was 0·3 mgm. per cent total and 0·1 mgm. per cent indirect. Coombs tests, both direct and indirect, were negative. The quantitative osmotic fragility curve showed a shift to the right, beginning at about 0·45 and being completed at about 0·2 per cent sodium chloride. There were no noteworthy findings on physical examination.

In paper electrophoresis, veronal buffer, *p*H 8·6, J. C.'s hæmoglobin sample resolved into two components (Fig. 1), one identical with hæmoglobin *A* and the other moving between hæmoglobins *G* and *S*. In chromatography on 'Amberlite, *IRC* 50', citrate buffer, *p*H 6·0 (ref. 7), J. C.'s hæmoglobin sample slowly separated into two components, one identical with hæmoglobin *A* and the other similar to *S*, but slightly faster, and with considerable 'tailing' towards *A* (Fig. 2). In contrast, hæmoglobin *L* moves between *S* and *C* in this method, and *P* does not separate from *A*, while Stanleyville I is indistinguishable from *S*.
